Abstract

It is well known that free (unconstrained) initial data for the gravitational field in general relativity can be identified on an initial hypersurface consisting of two intersecting null hypersurfaces. Here the phase space of vacuum general relativity associated with such an initial data hypersurface is defined; a Poisson bracket is defined, via Peierls' prescription, on sufficiently regular functions on this phase space, called "observables"; and a bracket on initial data is defined so that it reproduces the Peierls bracket between observables when these are expressed in terms of the initial data. The brackets between all elements of a free initial data set are calculated explicitly. The bracket on initial data presented here has all the characteristics of a Poisson bracket except that it does not satisfy the Jacobi relations (even though the brackets between the observables do).

The initial data set used is closely related to that of Sachs [Sac62]. However, one significant difference is that it includes a "new" pair of degrees of freedom on the intersection of the two null hypersurfaces which are present but quite hidden in Sachs' formalism. As a step in the calculation an explicit expression for the symplectic 2-form in terms of these free initial data is obtained.

1 Introduction

Canonical formulations of general relativity are usually couched in terms of initial data on spacelike hypersurfaces [ADM62][Sen82][Ash86]. However it has been widely

known since the early 1960's that the initial value problem on piecewise null hypersurfaces (hypersurfaces with null normal) is technically simpler than the spacelike initial value problem. The constraints reduce to ordinary differential equations, and *free* initial data, that parametrize the solutions to the constraints, can be identified explicitly [Sac62][Pen63][BBM62][Dau63].

A canonical formalism in terms of the free null initial data would be of interest for many reasons. It might offer insight into the properties of classical solutions of general relativity, it should provide a powerful framework for the numerical computation of these solutions and finally, in the context of quantum gravity, it promises to shed light on black hole entropy and the entropy bounds proposed by Beckenstein and Bousso [Bec73][Sus95][Bou99].

The main missing ingredient of such a formalism is the Poisson bracket on the space of free initial data. In 1978 Gambini and Restuccia [GR78], using a judiciously chosen coordinate system, were able to obtain a perturbation series in Newton's gravitational constant for the bracket between the main free data. The main data is a specification of the conformal equivalence class of the (degenerate) 3-metric on the initial data hypersurface. In Gambini and Restuccia's work, and in the present work, this is determined by the "conformal 2-metric", a field given on all of the initial data hypersurface, in contrast to the remaining data which lives on the intersection of the two null hypersurfaces only.

Here I will present closed form expressions for the brackets between all elements of a complete free initial data set for vacuum general relativity. Although the approach taken is entirely different from that of Gambini and Restuccia, the bracket between the conformal 2-metric at distinct points obtained is equal to that obtained by summing their series.

The first step in my approach is to define a Poisson bracket on a sufficiently rich family of sufficiently nice diffeomorphism invariant functions of the spacetime geometry of the Cauchy developments of the the initial data surface, which will be called "observables". These Poisson brackets are defined by Peierls' prescription, which, unlike other definitions of the Poisson bracket, involves no arbitrary elements of the classical description of the system (such as the choice of time, or the choice of fields), and which is directly related to the quantum commutator. The next step is to define a bracket on a suitable free initial data set so that it reproduces the Poisson brackets between the observables. This requirement is fulfilled if the bracket is a certain generalized inverse to the symplectic 2-form. It turns out to be possible to calculate such a generalized inverse explicitly, yielding explicit closed form expressions for the brackets between all data.

Unfortunately (at least from the point of view of a quantization project) the bracket obtained does not satisfy the Jacobi relations. The requirement that the bracket reproduce the Peierls brackets between observables seems absolutely neces-

sary. Nevertheless there still seems to be some freedom in the choice of bracket. Though the condition used here to determine the brackets on initial data is clearly *sufficient* to guarantee that the consequent brackets of observables reproduces the Peierls bracket, it is not clear that it is necessary. Some relaxation of this condition seems possible. Moreover, the brackets compatible with this condition are almost, but not quite, unique. The author is currently investigating whether a true Poisson bracket on initial data which reproduces the Peierls bracket on observables can be found.

Null hypersurfaces are always swept out by congruences of null geodesics, and these generically form caustics. It seems preferable, at least at this stage, to work with smooth and structurally simple null hypersurfaces, so the hypersurfaces have been truncated such that they contain no caustics. This requires us to work with initial data on hypersurfaces with boundary, which brings with it new problems. On the other hand, it seems very natural and appropriate to general relativity to describe it via an "atlas of phase spaces"[1] rather than to attempt to force it into a single phase space - thereby imposing global causality which, though comfortingly familiar, is entirely alien to the local nature of the theory.

Be that as it may, the presence of boundaries has frustrated all my attempts to obtain the brackets by more conventional means, and is the reason that the bracket is a generalized inverse of the symplectic 2-form instead of a true inverse. Here a generalized inverse of the symplectic 2-form inverts the action of this 2-form on phase space vectors corresponding to perturbations of the gravitational field that vanish in a neighbourhood of the boundary of the initial data hypersurface.

A variation of a solution can be represented as a variation of the initial data. However, for some initial data variables a variation of the solution metric that vanishes near the boundary of the initial data hypersurface may produce variations of the initial data that do not vanish near the boundary. This occurs for instance for Sachs' initial data. It depends on how the initial data at point is related to the metric field. However, to calculate the generalized inverse of the symplectic 2-form it is convenient to use free initial data fields that *are* invariant near the boundary under variations that leave the solution metric undisturbed in a neighbourhood of the boundary, or indeed under variations that simply leave the 4-geometry undisturbed in such a neighbourhood. This requirement has led me to define a new free initial data set, differing somewhat from that of Sachs. It contains a new field on the intersection of the two null hypersurfaces. The information in this field is contained in Sachs's data but rather implicitly. The inclusion of this field is quite important in the phase space formalism since it is essentially the canonical conjugate to another datum on the intersection 2-surface (which is included explicitly in the Sachs data).

[1] I thank J-A Zapata for this evocative phrase.

In the following section I define the initial data hypersurface and the associated phase space, observables and the Peierls bracket between them, and the auxiliary pre-Poisson bracket on initial data. The relation of the Peierls bracket and the symplectic 2-form is found, and also the sufficient condition ensuring that the bracket on initial data reproduces the Peierls bracket on observables. The symplectic 2-form corresponding to the Einstein-Hilbert action is calculated explicitly in terms of the spacetime metric. Finally, the meaning of gauge invariance for initial data on a hypersurface with boundary is considered. In section 3 some convenient spacetime coordinate systems adapted to the geometry are presented and an initial data set suitable for our purposes is proposed and demonstrated to be free and complete. This section also contains a treatment of the relation between the variations of field components referred to different coordinate systems that are adapted to the fields. Then, in section 4 the symplectic 2-form is expressed in terms of the initial data chosen. Finally, in section 5 the brackets between the free initial data are calculated in closed form.

I close the paper with some concluding remarks about open issues and potential directions of research in section 6.

2 Covariant canonical theory

2.1 The problem

General relativity is a local theory in the sense that initial data in a bounded region of space - a bounded achronal hypersurface in spacetime - suffices to determine completely the gravitational field in a contiguous spacetime region, the causal domain of dependence[2] of the hypersurface. It does not matter what is happening in the rest of the universe. We may thus focus attention on this domain of dependence and regard the space of values of the initial data on the hypersurface as a space of states, or phase space, of the gravitational field in the domain of dependence.

Now in General Relativity diffeomorphic solutions to Einstein's field equations are equivalent, i.e. they represent the same predictions concerning measurements. Thus the phase space, which we shall denote Φ, actually consist of the equivalence classes of initial data sets corresponding to diffeomorphic solutions. Equivalently, it may be identified with the space of diffeomorphism equivalence classes of maximal Cauchy developments[3] of data on the given hypersurface.[4]

[2] Achronal sets and domains of dependence are defined in appendix A, see also [HE73] or [Wald84].

[3] The, slightly generalized, definition of Cauchy developments, used here as well as that of maximal Cauchy developments, is given in appendix A. For the sake of simplicity we shall only consider C^∞ developments.

[4] Φ is often called the "physical" or "reduced" phase space to distinguish it from the larger

The aim of the present work is to find the Poisson bracket on the phase space Φ corresponding to an initial data hypersurface consisting of two intersecting null hypersurfaces.

What will actually be obtained is the Poisson bracket on a particularly nice subset of functions on this phase space, which in turn suffices to determine, almost uniquely, the brackets between initial data. The brackets between the initial data obtained define a *pre-Poisson bracket* on the algebra of phase space functions, that is, a bracket having all the properties of a Poisson bracket save that it does not necessarily satisfy the Jacobi relation. The lack of a Jacobi relation is of course an important issue when considering the quantization of the system, since commutators satisfy this relation identically.

Let us define precisely the initial data hypersurface to be considered. It is a compact manifold (with boundary and edges),[5] $\mathcal{N}$, consisting of two null hypersurface branches $\mathcal{N}_L$ and $\mathcal{N}_R$ joined on a smooth spacelike 2-surface S_0 diffeomorphic to a disk (See Fig. 1). $\mathcal{N}_L$ and $\mathcal{N}_R$ are swept out by the two congruences of future directed null geodesics (called *generators*) emerging normally from S_0, and are truncated at spacelike disks - S_L and S_R respectively - before these generators form caustics.

From the point of view of the initial value problem $\mathcal{N}$ is simply a compact 3-manifold with boundary, consisting of two 3-cylinders ($\mathcal{N}_L$ and $\mathcal{N}_R$) joined end to end on the 2-surface S_0. The initial data consists of smooth 3-metrics specified on $\mathcal{N}_L$ and $\mathcal{N}_R$, with a continuity condition at S_0, and some further quantities specified on S_0 only (see subsection 3.2). In order that the branches $\mathcal{N}_L$ and $\mathcal{N}_R$ be null in the solution matching the data, the 3-metric on each branch must be degenerate. That is, there must exist at each point a degeneracy vector, a vector tangent to the branch that is orthogonal to all tangent vectors, which corresponds to the null direction tangent to the embedding of the branch in spacetime. Moreover, the space of such degeneracy vectors must be one dimensional at any point at which the branch is embedded smoothly (which requires that the tangent vectors to the branch are mapped to a three dimensional subspace of the spacetime tangent space). In fact the metric on a cross section transverse to the degeneracy vectors must be positive definite. Requiring these conditions to hold at all points of $\mathcal{N}_L$ and $\mathcal{N}_R$ is equivalent to requiring that the generators form no caustics on $\mathcal{N}$. See appendix B.

Now let us consider the maximal Cauchy developments of data on $\mathcal{N}$. The representation of a initial data set, or phase point, by its Cauchy development will play a central role in the definition of Poisson brackets for the following reason: Recall

"kinematic" phase space K, constructed without use of the field equations. (see for example [HT92]. A geometrical construction of K for asymptotically flat and for compact boundaryless spacetimes is given in [LW90]). The Poisson bracket we are looking for - the Poisson bracket on the physical phase space Φ, expressed directly in terms coordinates on Φ - is often called the Dirac bracket.

[5] Manifolds with boundary and edges are defined in appendix A.

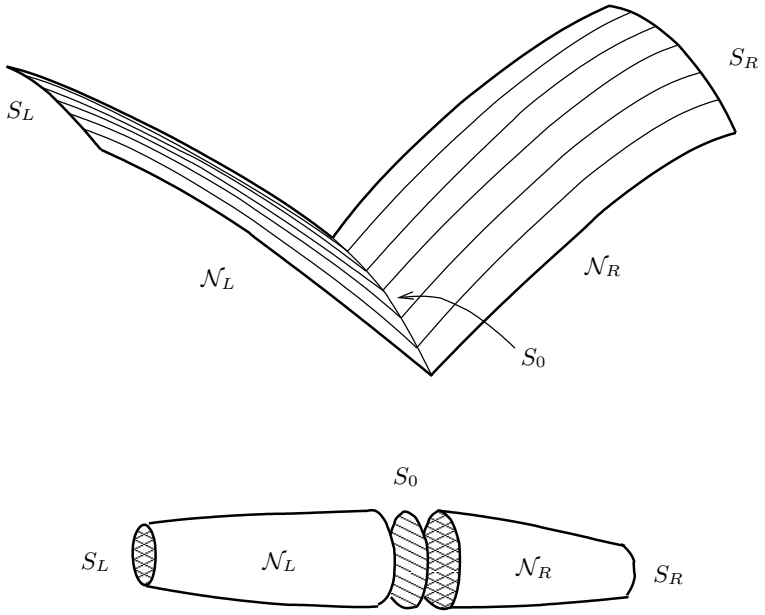

Figure 1: The upper diagram shows an initial data surface like $\mathcal{N}$ embedded in a 2+1 dimensional spacetime. In 3+1 dimensional spacetimes each of the components $\mathcal{N}_L$, $\mathcal{N}_R$, and S_0, of course have one dimension more than shown in this diagram. This is shown in the lower diagram, which depicts a three dimensional hypersurface $\mathcal{N}$ corresponding to a $3+1$ spacetime. Unlike the upper diagram, the lower diagram represents only the intrinsic differential topology of $\mathcal{N}$, and does not indicate it's embedding in spacetime.

that the bracket of two phase space functions is again a function on phase space, and therefore takes as its argument a phase point. It turns out that the value of the Poisson bracket at a phase point can be very naturally defined in terms of the spacetime geometry of the maximal Cauchy development corresponding to that phase point. The fundamental definition involves only retarded and advanced Green's functions for the linearized Einstein equation on this Cauchy development.

But how do we know that Cauchy developments of a given set of data on $\mathcal{N}$ actually exist? Rendall [Ren90] has proved for a particular set of initial data variables, equivalent to that we shall use, that if these data are smooth on $\mathcal{N}$ they determine a C^∞ Cauchy development of at least a neighbourhood $\tilde{\mathcal{N}} \subset \mathcal{N}$ of S_0 in $\mathcal{N}$. In fact Rendall's proof, which reduces the initial value problem on $\mathcal{N}$ to an equivalent initial value problem for data on a spacelike hypersurface, combined with standard results on the spacelike initial value problem ([Wald84] Theorem 10.2.2), implies that the data on $\tilde{\mathcal{N}}$ determines a smooth maximal Cauchy development uniquely up to diffeomorphisms.

I shall assume that Rendall's results in fact apply to all of $\mathcal{N}$, i.e. $\tilde{\mathcal{N}}$ can be taken to be all of $\mathcal{N}$, assumption which I consider very likely to be correct. If it is *not* then the results are still valid if $\mathcal{N}$ is replaced by a subset $int\tilde{\mathcal{N}}$ - which is entirely equivalent, by diffeomorphism invariance, to placing additional conditions on the initial data on $\mathcal{N}$.

This assumption implies that there exists a smooth boundaryless, globally hyperbolic[6] metric manifold M containing $\mathcal{N}$ and its Cauchy development isometrically in its interior.[7] [8]

Indeed, in the present work a Cauchy development shall be defined as the domain of dependence of the initial data hypersurface embedded achronally in a manifold with a metric that satisfies Einstein's equation, at least within the domain of dependence

[6] Global hyperbolicity is defined in appendix A.

[7] Rendall embeds $\mathcal{N}$ in $\mathbb{R}^4$ and then shows that there exists a smooth Lorentzian metric g' on $\mathbb{R}^4$ such that g' to the past of $\mathcal{N}$ smoothly matches any Cauchy development (on $\mathbb{R}^4$) of the initial data to the future of $\mathcal{N}$. g' and a Cauchy development spliced together in this way defines a smooth metric on an open connected subset U of $\mathbb{R}^4$ excluding $\partial\mathcal{N}$ but including $int\mathcal{N}$ such that $U - \mathcal{N}$ is not connected. Now the initial data used by Rendall is free. The only condition it must satisfy is smoothness. Thus it may be extended to a larger hypersurface $\mathcal{N}^+$, of the same form as $\mathcal{N}$, but containing $\mathcal{N}$ in its interior. There thus exists a boundaryless metric manifold U^+ containing all of $\mathcal{N}$ which extends the Cauchy development of $\mathcal{N}$. The results of appendix B, which take as a starting point that $\mathcal{N}$ is embedded achronally in a boundaryless Lorentzian metric manifold therefore apply. In that appendix it is shown that $\mathcal{N}$, and its maximal Cauchy development, are contained isometrically in a smooth, boundaryless metric manifold M which is globally hyperbolic (see prop. B.20).

[8] ∂X will always denote the boundary component of X viewed as a manifold with boundary. See appendix A. This boundary will in general differ from the topological boundary of the embedding of X in another manifold.

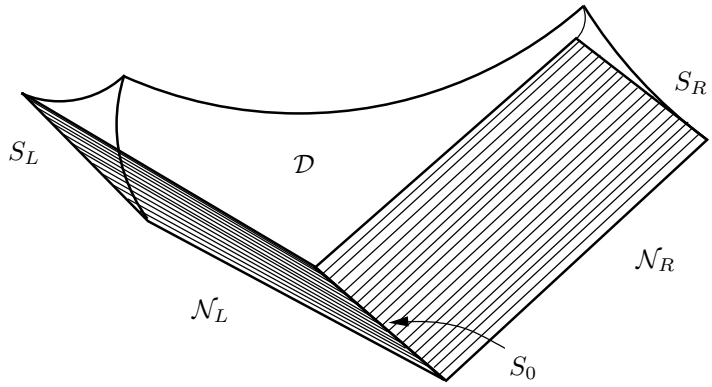

Figure 2: The domain of dependence of a pair of plane null rectangles in $2+1$ dimensional Minkowski space is shown. The straight lines ruling the rectangles are the generators. The domain of dependence is bounded to the future by the light cones of the two ends of S_0 and the null surfaces orthogonal to S_R and S_L.

(see def. A.11). Note that the domain of dependence $D[\mathcal{N}]$ of $\mathcal{N}$ is not in general a manifold, not even a manifold with boundary. On the other hand $\mathcal{D} \equiv intD[\mathcal{N}]$, the interior of $D[\mathcal{N}]$, and $int\mathcal{N}$ together do form a manifold with boundary, $\underline{\mathcal{D}}$. $\underline{\mathcal{D}}$ with its metric is essentially the whole Cauchy development. The underline in $\underline{\mathcal{D}}$ is meant to represent the fact that $\underline{\mathcal{D}}$ consists of $\mathcal{D}$ and its past boundary. (Prop. B.11 indicates that $D[\mathcal{N}]$ consists entirely of the future domain of dependence of $\mathcal{N}$.) $\underline{\mathcal{D}}$ may also be thought of as $D[\mathcal{N}]$ minus its future Cauchy horizon (prop. B.22).[9]

By prop. B.23 the subsets $\underline{\mathcal{D}}$ of all Cauchy developments, of distinct data, are diffeomorphic as manifolds (though of course not in general isometric). They are thus all diffeomorphic to a particular such manifold, $\underline{\mathcal{D}}_0$, which we may take to be the union of the interior of the hypersurface $\mathcal{N}_0 = \{t = |x|, |x| \leq 1, y^2 + z^2 \leq 1\}$ and the interior of its domain of dependence in $\mathbb{R}^4$ equipped with the Minkowski metric $ds^2 = -dt^2 + dx^2 + dy^2 + dz^2$ - see Fig. 2.

[How can one be certain that $\mathcal{N}$, equipped with given initial data is indeed achronally embedded in the solution space. This question also arises in the spacelike Cauchy problem, but it becomes especially urgent when the initial data hypersurface is piecewise null, like $\mathcal{N}$, because the generators will generally cross eventually, spoiling the achronality of the hypersurface they sweep out (by the corollary to theorem 8.1.2. of [Wald84]). Truncating the generators before a caustic is formed does not exclude the possibility that *non-neighbouring* generators intersect. (See Fig. 3). Thus it seems one would have to truncate the generators prior to any crossing, and

[9] Cauchy horizons are defined in appendix A.

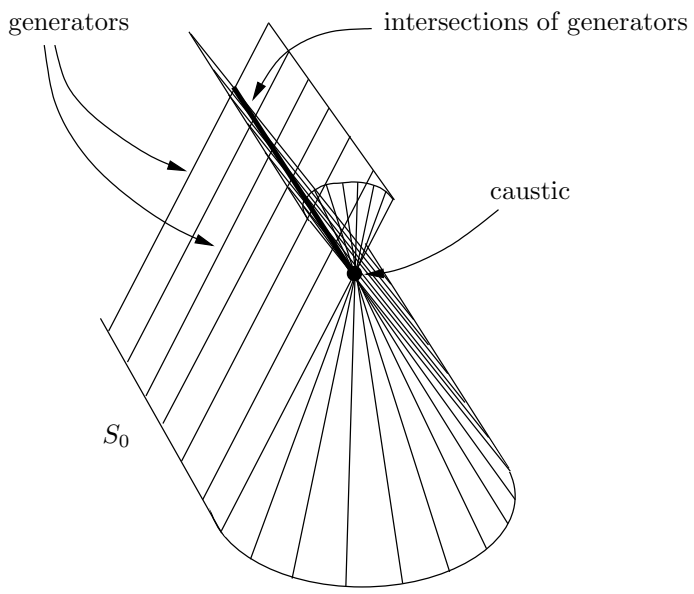

Figure 3: An example of caustics and intersections of generators. S_0 is a spacelike curve in $2+1$ dimensional Minkowski spacetime having the shape of a half racetrack) - a semicircle extended at each end by a tangent straight line. The congruence of null geodesics normal to S_0 and directed to the future and inward - the generators shown in the diagram - sweep out a null surface having the form of a ridge roof, terminated by a (half) cone over the semicircle. The generators from the semicircle form a caustic at the vertex of the cone. There neighbouring generators intersect. On the other hand generators from the two straight segments of S_0 cross on a line (the ridge of the roof) starting at the caustic, but the generators that cross there are not neighbours at S_0.

the question arises how this requirement can be expressed as a restriction on the admissible initial data.

It turns out that that is not necessary. Suppose $\mathcal{N}$ is swept out by the two future directed null geodesic congruences normal to a spacelike disk in a spacetime X, as per its definition, and that it contains no caustics of the generators. (Suitable restrictions on the initial data do assure that - see prop. B.4.) Then if the generators of $\mathcal{N}$ cross, there always exists another spacetime, forming a locally isometric covering of a neighbourhood of $\mathcal{N}$ in X, in which the generators do *not* cross and the $\mathcal{N}$ is achronal. See appendix B, and in particular prop. B.6. Thus no restriction on the initial data is necessary to ensure the achronality of $\mathcal{N}$. Moreover, the solutions in which $\mathcal{N}$ has self intersections and is not achronal are represented in the phase space of Cauchy developments by covering manifolds.

A subtlety arises in connection with the Poisson brackets, which are defined in terms of small perturbations of the spacetime geometry. The small perturbations of the geometry of a non simply connected spacetime X are distinct from the small perturbations of its covering manifold $\tilde{X}$. Nevertheless it seems that if one is careful to identify functions of the geometry of X with functions of the the geometry of $\tilde{X}$ that are invariant under the action of the fundamental group of X on $\tilde{X}$ then the brackets between such functions calculated in X are equal to those calculated between the corresponding quantities in $\tilde{X}$.]

All of the Cauchy developments can therefore be represented up to diffeomorphisms by metrics on the single, fixed manifold $\underline{\mathcal{D}}_0$. Mapping the metric on $\underline{\mathcal{D}}$ in each Cauchy development to $\underline{\mathcal{D}}_0$ via the diffeomorphism of prop. B.23 one obtains a space $\mathcal{S}_0$ of solutions to Einsteins equations representing the Cauchy developments. The diffeomorphism equivalence classes of solutions in $\mathcal{S}_0$ form the phase space Φ.

The fact that each metric in $\mathcal{S}_0$ is (diffeomorphic to) a maximal Cauchy development of null initial data on $\mathcal{N}$ is equivalent to the requirement that it be a solution such that $int\mathcal{N}_0 \subset \underline{\mathcal{D}}_0$ is null in the solution metric and the interior of $\underline{\mathcal{D}}_0$ is the interior of the domain of dependence of $int\mathcal{N}_0$ in $\underline{\mathcal{D}}_0$, and also in any smooth extension of $\underline{\mathcal{D}}_0$ and its metric that satisfies the field equation. (The final condition ensures maximality.)

There is a further condition the metrics in $\mathcal{S}_0$ must satisfy. As we have seen, our assumptions regarding the initial value problem on $\mathcal{N}$ imply that the metric of the Cauchy development can be smoothly extended to a boundaryless manifold M containing $\mathcal{N}$, and in particular $\partial\mathcal{N}$. This gives rise to a restriction on the metrics in $\mathcal{S}_0$. If $\underline{\mathcal{D}} \cup \partial\mathcal{N}$ in M is diffeomorphic to $\underline{\mathcal{D}}_0 \cup \partial\mathcal{N}_0$ in $\mathbb{R}^4$ then the restriction is simply that the solutions in $\mathcal{S}_0$ must be smoothly extendible to $\partial\mathcal{N}_0$ in $\mathbb{R}^4$. However we have not proved that these sets are diffeomorphic, only that $\underline{\mathcal{D}}$ and $\underline{\mathcal{D}}_0$ are, so the

form this restriction takes in $\mathcal{S}_0$ is not known with certainty at present.[10]

The requirement of smoothness at $\partial\mathcal{N}$ is relevant to the analysis of gauge transformations in subsection 2.3. In the definition of Poisson brackets, which is our main focus of interest, the issue can be sidestepped. The value of a Poisson bracket $\{A, B\}$ at a given solution, or phase point, g involves only the variations of the quantities A and B under perturbations about the given fiducial solution. It is thus natural to work with metric fields living on the spacetime manifold M_g of this fiducial solution, or on the domain of dependence of $\mathcal{N}$ in M_g, rather than on Minkowski space or on the domain of dependence of $\mathcal{N}_0$ in Minkowski space. $\mathcal{S}$ shall be the space of maximal Cauchy developments (or "solutions" for short) mapped diffeomorphically to $\underline{\mathcal{D}}_g$, in complete analogy with $\mathcal{S}_0$. $\mathcal{F}$ shall be the vector space of all smooth metric fields on M_g.

Of course, basing the description on $\underline{\mathcal{D}}_g$ and M_g, rather than on $\underline{\mathcal{D}}_0$ and Minkowski space, does not by itself resolve the issue of boundary conditions at $\partial\mathcal{N}$ for metrics other than the fiducial solution metric. One is just replacing one preferred solution, Minkowski space, by another, g. However, it does allow the issue to be resolved for the small perturbations relevant to the definition of the bracket. We shall see that the Poisson bracket $\{A, B\}$ of real valued functions A and B on $\mathcal{F}$ involves the variations of A and B under perturbations of the metric in the space, L_g, of smooth solutions on M_g to the field equation linearized about g.[11] [12] (see (7) or (10)).

In the sequel the only M and $\underline{\mathcal{D}}$ considered will be those of the fiducial solution (whichever solution this is), so the subscript g will be dropped.

It should be emphasized that while diffeomorphic metric fields may be considered physically equivalent they are not the *same* in our mathematical model. A manifold X consists of distinct *a priori* identifiable points (see the definition of manifolds in,

[10] What conceivably might happen, though I believe it cannot, is that on some generator from ∂S_0 the future boundary of $\underline{\mathcal{D}}$ in M is not only tangential to $\mathcal{N}$ on the generator, as it is in flat spacetime, but it meets $\mathcal{N}$ so "softly" that also the second derivatives (of spacetime coordinates) are equal on the two hypersurfaces.

[11] The linearized field equation has well defined solutions on all of M_g even though the metric g need be a solution to the (vacuum) Einstein equation only on $D[\mathcal{N}]$.

[12] Note that if g is linearization stable then the space, $L_g|\underline{\mathcal{D}}$, of solutions to the linearized field equations in L_g, restricted to $\underline{\mathcal{D}}$, is identical with the space T_g of tangents to the space of solutions to the full field equations on $\underline{\mathcal{D}}$. At a solution that is not linearization stable $L_g|\underline{\mathcal{D}}$ is larger than T_g.

T_g is essentially the tangent space to $\mathcal{S}$ at $g \in \mathcal{S}$. The solutions in $\mathcal{S}$ are restricted by the requirement that the metric on $\underline{\mathcal{D}}$ be a maximal Cauchy development of null data on $\mathcal{N}$, but in fact any variation of the solution about $g \in \mathcal{S}$ (i.e. any variation in T_g) can be made to respect these restrictions by adding suitable diffeomorphism generators, so the tangent space to $\mathcal{S}$ is T_g with a certain "diffeomorphism gauge fixing".

It seems likely that most Cauchy developments of data on $\mathcal{N}$ are linearization stable. Moncrief [Mon75] has shown that Cauchy developments of compact spacelike Cauchy surfaces without boundaries are linearization stable iff they have no Killing vectors.

for example [Wald84]) and it makes sense mathematically to speak of the value of the metric at the same point for different metric fields. This means that one may also distinguish adapted coordinate systems, such as Riemann normal coordinates, which depend on the metric placed on X, from fixed coordinates, which do not and are so to speak "painted on the points of X". It also means that the variation $\delta g_{\mu\nu}(p)$ of the metric at a point p is meaningful, a fact which we shall use implicitly when formulating general relativity in terms of a variational principle and in the associated definitions of the symplectic structure and the Poisson bracket of the theory.

Free initial data on $\mathcal{N}$ provide a convenient coordinate system on the phase space. By definition each valuation of such data corresponds to a solution - that is, the data are not subject to constraints - and this solution is uniquely determined, up to diffeomorphisms, on $D[\mathcal{N}]$. The algebra of functions on the phase space Φ is thus represented by the algebra of functions of the initial data,[13] and the (pre-)Poisson bracket can be specified explicitly by giving the brackets between the initial data.

Free initial data on piecewise null hypersurfaces have been found by several authors [Sac62][Pen63][BBM62][Dau63]. Sachs [Sac62] in particular has proposed a set of free initial data suitable for $\mathcal{N}$, and has argued (somewhat heuristically) that the values of these data determine the solution in a neighbourhood of $\mathcal{N}$ in $\underline{\mathcal{D}}$ uniquely up to diffeomorphisms. Rendall [Ren90] has proved that these data, if C^∞ on each of the null branches $\mathcal{N}_L$ and $\mathcal{N}_R$ of $\mathcal{N}$ and continuous in a suitable sense at S_0, indeed determine a C^∞ solution uniquely up to diffeomorphisms in a neighbourhood of S_0 in $\underline{\mathcal{D}}$. This is somewhat weaker than what is needed, but it does support Sachs' original claim. Here, as already stated earlier in other words, it will be assumed that Sachs' data determine the solution, modulo diffeomorphisms, on all of $\underline{\mathcal{D}}$. The brackets will be calculated between the elements of an initial data set, defined in subsection 3.2, that is equivalent to, but slightly different from Sachs' data.

To be exact, in the present work the pre-Poisson bracket on initial data will be

[13] Some distinct data sets define diffeomorphic solutions, so the initial data will be multivalued as functions on Φ. A function of initial data that represents a function on Φ must of course have the same value on all data sets that correspond to a given diffeomorphism equivalence class of solutions, that is, on all *equivalent* initial data sets. When using the ADM spacelike initial data [ADM62] or the Sen-Ashtekar variables [Sen82] [Ash86] to represent functions on the physical phase space this requirement - the requirement that the functions be gauge invariant - is highly non-trivial, since finding the class of initial data sets equivalent to a given set requires solving Einstein's field equations. Here the freedom in the data corresponding to a given diffeomorphism equivalence class of solutions amounts only to the freedom to change coordinates on the two spacelike disks S_L and S_R, and in this way relabel the generators of $\mathcal{N}_L$ and $\mathcal{N}_R$. The action of these transformations on the initial data is simple and explicitly known - it does not require the solution of the field equations - so the multivaluedness of our initial data should not represent a problem. It is an interesting and open question whether this freedom in our data should be understood as a gauge freedom (generated by some sort of constraint?) or rather as a global symmetry.

evaluated at C^∞ solutions without Killing vectors such that the generators of a given branch, $\mathcal{N}_L$ or $\mathcal{N}_R$, of $\mathcal{N}$ are either everywhere converging or everywhere diverging. The last condition ensures that the cross sectional area of a bundle of neighbouring generators is either monotonically increasing or monotonically decreasing, which makes it possible to use the so called area distance, a quantity proportional to the square root of this cross sectional area, to parametrize the generators.

The corresponding limitation on the applicability of our formulae for the bracket on initial data is far weaker than one might think. Causality requires that the Poisson bracket between two observables is non-zero only if these depend on fields at causally related points (points connected by a causal curve), and it is natural (as will be discussed further on) to require the same for the brackets between initial data. On $\mathcal{N}$ causally related points must lie on the same generator (by prop. B.7), so the only non-trivial brackets between data on $\mathcal{N}$ are those between data on the same generator. Now suppose that the monotonicity conditions on the cross sectional area of bundles of generators does *not* hold for $\mathcal{N}$, and suppose $p \in intS_0$ is the origin of a generator on which we wish to evaluate a bracket. If the generators of both $\mathcal{N}_L$ and $\mathcal{N}_R$ have non-zero expansion rates at p, which generically is the case, then we can find a disk $S_0' \subset S_0$ containing p in its interior on which these expansion rates are everywhere non-zero and of uniform sign. Our results then apply to a hypersurface $\mathcal{N}'$ swept out by the generators emerging from S_0', for if the expansion rate at p is negative then the Raychaudhuri equation guarantees that it remains negative along the generators until a caustic, or conjugate point, is reached, while if the expansion rate is positive the generators may be cut off before they begin to reconverge. Thus our results give the bracket between the data except when the expansion rate of the generators of $\mathcal{N}_L$ or $\mathcal{N}_R$ vanish at p, or when one of the initial data in the bracket pertains to a point which lies beyond the cutoff of $\mathcal{N}'$ because the neighbouring generators, initially diverging at S_0, have begun to reconverge. In fact, in the case of re converging generators the formulae we will find for the brackets of initial data are still meaningful and can be used to assign values to these. If the expansion rate of the generators vanishes at p the expressions obtained for the brackets of some of the data are still meaningfully but other brackets are singular. Whether any of these extrapolations are correct remains to be determined since these cases are not treated in the present derivation of the bracket.

As the fundamental definition of the physical Poisson bracket an adaptation to general relativity of the Peierls bracket [Pei52] will be adopted. Let g be a solution to the field equations and let A and B be diffeomorphism invariant functionals of the metric, and suppose that the functional gradient $\delta A/\delta g^{\mu\nu}$ of A has compact support in spacetime. [The support of $\delta A/\delta g^{\mu\nu}$ will be called the *domain of sensitivity* of A, and will be denoted by s_A.] The value of the Peierls bracket $\{A, B\}$ at g is determined by the first order perturbation of the solution, and thus of the value of B, caused by

the addition of a term proportional to A to the action, I. Of course the perturbation of the metric is not determined uniquely by the change in the action. Aside from the freedom to apply diffeomorphisms, one may choose a retarded perturbation, an advanced perturbation, or a combination of these. Let g^+ be a solution to the field equations corresponding to the modified action $I_\lambda = I + \lambda A$ (with λ a real constant) which equals g outside the causal future (domain of influence) $J^+[s_A]$ of s_A and g^- a solution that agrees with g outside the causal past $J^-[s_A]$ of s_A.[14] (That is, g^+ is the solution with a retarded perturbation, while g^- incorporates an advanced perturbation.) Then the Peierls bracket is

$$\{A, B\} = \Delta_A B = \frac{d}{d\lambda} B(g^+_\lambda)|_{\lambda=0} - \frac{d}{d\lambda} B(g^-_\lambda)|_{\lambda=0}. \tag{1}$$

As the action for gravity we will use the Einstein-Hilbert action,[15]

$$I = \frac{1}{16\pi G} \int_Q R\sqrt{-g}\, d^4x, \tag{2}$$

where Q is the spacetime domain of integration of the action, R the scalar curvature defined by the spacetime metric $g_{\mu\nu}$, g the determinant of this metric, and d^4x the coordinate volume form in a coordinate system x fixed in the manifold Q.

No boundary terms need be added to the action because boundary terms do not affect the Poisson bracket implicit in the action. (See [LW90] for a discussion of the effect of boundary terms on the presymplectic 2-form, and sub-subsection 2.2.1 for the relation between the presymplectic 2-form and the Peierls bracket.)

This definition of the Poisson bracket has the virtue of being manifestly covariant and, moreover, is very directly related to the commutators of quantum theory. Peierls showed that for field theories in Minkowski space his bracket is equal to that computed from the conventional Poisson bracket on initial data. Further on I will show that this bracket has all the properties of a Poisson bracket, including antisymmetry and the Jacobi relation, which are not obvious from the expression (1). In fact it will be argued that the Peierls bracket between diffeomorphism invariant (and sufficiently smooth) functions of the spacetime geometry is equal to the conventional Poisson bracket between these functions implied by the Poisson brackets between the canonical ADM variables on a spacelike Cauchy surface [ADM62].

[14] The causal past and future are defined in appendix A.

[15] The normalization of the action is chosen so that when a particle of mass m is coupled to the gravitational field with it's action normalized so that the canonical momentum of the particle is $m\, dx^\mu/d\tau$, with τ the proper time of the particle, then Newton's law of gravitation (with G = Newton's constant) is recovered in the appropriate limit. The sign conventions for the curvature tensor and scalar are those of [Wald84], that is, $R = R_{\mu\nu}{}^{\mu\nu}$ with $[\nabla_\mu, \nabla_\nu]\omega_\sigma = R_{\mu\nu\sigma}{}^\rho \omega_\rho$ for any 1-form ω.

Unfortunately the initial data on $\mathcal{N}$ used in the present paper are too singular as functions of the spacetime geometry to allow an unambiguous, direct computation of the Peierls bracket between them. My approach is therefore to use Peierls' definition to define the bracket on a set of sufficiently regular diffeomorphism invariant functions of the metric on $\underline{\mathcal{D}}$, which will be called "observables", and then to look for a bracket on the initial data which reproduces the Peierls bracket on the observables when these observables are expressed as functions of the initial data.

I shall call a functional A of the metric on $\underline{\mathcal{D}}$ an *observable* if it is diffeomorphism invariant and its functional gradient $\alpha_{\mu\nu} = \frac{1}{\sqrt{-g}}\frac{\delta A}{\delta g^{\mu\nu}}$ is C^∞ and of compact support contained in the interior of $\underline{\mathcal{D}}$. The support of α is of course the domain of sensitivity of A.

If all measurable functions of the metric are observables in this sense then our approach is certainly justified because the only predictive content of a field theory is what it has to say about measurable quantities. The predictive content of a classical field theory consists of the relations between measurable functions of the fields implied by the field equations. In addition if the field theory is derived from a local action, like general relativity is, then the action defines a Poisson bracket between the measurable functions of the classical fields which reflects the commutation relations of the corresponding quantum observables.[16] A classical field theory contains no further information about the classical world it models or the quantum world which might underlie this classical world. In particular the initial data and their brackets are no more than a means to represent the measurable quantities and their brackets.

Thus, in a mathematical formulation of a field theory in terms of observables these should be nice enough, as functions of the field, that the Poisson bracket between them can be defined, and yet rich enough so that all measurable quantities are represented by observables, or at least the limits of sequences of observables. Furthermore it is at least convenient and probably necessary that the Poisson brackets of observables are themselves observables, so that the observables form a closed Poisson algebra.

It is not clear that the class of observables we have defined above meet these criteria,[17] but it is reasonable to expect that our observables form at least a subset of an algebra of observables of general relativity that does, and, as we shall see, there

[16] The same classical theory can sometimes be derived from distinct actions that define distinct Poisson brackets, for instance in the case of the harmonic oscillator. This presumably means that there are also distinct quantum systems which behave according to this classical theory in the classical limit. The Poisson structure is merely a convenience at the classical level which allows one to put theories into a universal (canonical) form. It assumes physical significance only at the quantum level.

[17] It is not hard to see that the domain of sensitivity of the Peierls bracket of two of our observables is compact and contained in the interior of $\underline{\mathcal{D}}$. However it is not obvious that the functional gradient of the bracket must be C^∞ in spacetime.

are enough of them so that their Peierls brackets, together with a reasonable causality condition, determine almost unique brackets between our null initial data.

Do observables as defined above in fact exist? An example shows that they do: For a generic C^∞ metric g on $\underline{\mathcal{D}}$, and a point p in the interior of $\underline{\mathcal{D}}$, C^∞ coordinates consisting of scalars formed from the curvature can be found which are non-singular on a neighbourhood of p. Choose a compact domain $c_0 \subset \mathcal{D}$, with non-empty interior, in this neighbourhood and let $[c] \subset \mathbb{R}^4$ be the coordinate range corresponding to c_0. Then for all metrics in a suitable neighbourhood $U \subset \mathcal{F}$ of g, in which all components of the metric with respect to the curvature scalar coordinates are nearly equal to those of g throughout the coordinate range $[c]$, the same curvature scalars continue to be good spacetime coordinates on the pre-image c of $[c]$ and this pre-image will be a compact subset of $\mathcal{D}$ diffeomorphic to c_0.

Now note that the metric components taken in these coordinates are diffeomorphism invariants. Suitable functionals of these metric components on $[c]$ define observables. The domain of sensitivity of such a functional is necessarily a closed subset of c, and thus a compact subset of the interior of $\underline{\mathcal{D}}$. [The functional gradient of such a functional, A, vanishes outside c because a smooth infinitesimal variation of the metric which vanishes on c leaves the curvature scalars invariant on c and changes them only smoothly and infinitesimally outside c. This implies that A is unchanged because the preimage of $[c]$ remains unchanged (i.e. equal to c) and the metric components with respect to the curvature scalar coordinates are unchanged in $[c]$.] It is not difficult to construct explicitly a functional A of this form so that its functional gradient exists, for metrics in U, and is C^∞ in spacetime. For instance, if x^μ are manifold fixed coordinates, z^α are curvature scalar coordinates, and f is a smooth function from $\mathbb{R}^4$ to $\mathbb{R}$ that vanishes outside $[c]$ then

$$A = \int_{[c]} f(z)\sqrt{-det[g_{\alpha\beta}](z)}d^4z = \int_c f(z(x))\sqrt{-det[g_{\mu\nu}](x)}d^4x \tag{3}$$

satisfies all requirements. (It is less obvious how to construct observables that are well defined on all of $\mathcal{F}$, or $\mathcal{S}$, and still satisfy our requirements, but that is not necessary here.)

For non-generic metrics g which have Killing vectors the situation seems to be different. The construction of functionally differentiable observables which distinguish between metrics with isometries (Killing vectors) seems to be problematic. Perhaps this should not surprise us since the quotient manifold of the space of metric fields $\mathcal{F}$ by the group of diffeomorphisms of $\underline{\mathcal{D}}$ is singular at metrics with isometries. Notice also that observables that are actually measured are always defined using some sort of inhomogeneity or asymmetry, if not in the metric then in the matter fields, to single out points or regions of spacetime. Recall that metrics with isometries are explicitly excluded from the scope of the present work.

The definition (1) of the Peierls bracket has one serious problem: It is in general not obvious that the exact stationary points g^+ and g^- of the modified action $I + \lambda A$ actually exist. Fortunately this problem is easily overcome. The exact stationary points g^+ and g^- are not really necessary in order to define the Peierls bracket. The first order (in λ) approximations to these are sufficient. The Peierls bracket is a creature of first order perturbation theory and is well defined whenever this theory is: Exact stationarity of the modified action requires

$$G_{\mu\nu} + 16\pi G\lambda\alpha_{\mu\nu} = 0 \tag{4}$$

where $G_{\mu\nu} = R_{\mu\nu} - 1/2 g_{\mu\nu}R$ is the Einstein tensor. This is just Einstein's field equation with stress energy tensor $-2\lambda\alpha_{\mu\nu}$. [The diffeomorphism invariance of A implies that $\alpha_{\mu\nu}$ is divergenceless, as the stress energy tensor in Einstein's equation must be: For any C^∞ vector field χ

$$0 = \pounds_\chi A = -2\int_{\mathcal{D}} \alpha_{\mu\nu}\nabla^\mu\chi^\nu\sqrt{-g}\, d^4x = 2\int_{\mathcal{D}}[\nabla^\mu\alpha_{\mu\nu}]\chi^\nu\sqrt{-g}\, d^4x \tag{5}$$

and thus $\nabla^\mu\alpha_{\mu\nu} = 0$.[18]]

On the other hand, if g is a solution to Einstein's vacuum equation $G_{\mu\nu} = 0$, then the modified action is stationary to first order in λ at $g + \lambda\delta_A g$ provided

$$\delta_A G_{\mu\nu} + 16\pi G\alpha_{\mu\nu} = 0. \tag{6}$$

Here δ_A acting on a functional of the metric is the linear order variation of the functional due to the variation $\delta_A g$ of the metric.

The Peierls bracket of two observables A and B may be defined by

$$\{A, B\} = \Delta_A B \tag{7}$$

with

$$\Delta_A = \delta_A^+ - \delta_A^- \tag{8}$$

where $\delta_A^+ g$ and $\delta_A^- g$ are solutions to (6) that vanish outside $J^+[s_A]$ and $J^-[s_A]$ respectively.

When the exact solutions g^+ and g^- exist then $dg^\pm/d\lambda$ satisfies the conditions defining $\delta_A^\pm g$, so the definition (1) of $\{A, B\}$ is consistent with (7) and (8). The advantage of the definition via (7) and (8) is that one can show that $\delta_A^+ g$ and $\delta_A^- g$ always exist, provided A is an observable (α is C^∞, divergenceless, and of compact support contained in the interior of $\underline{\mathcal{D}}$), and is unique up to diffeomorphisms, assuring

[18]Conversely, if A is defined on a diffeomorphism invariant domain of metric fields in $\mathcal{F}$ and α is divergenceless on all of this domain, A is diffeomorphism invariant.

the existence and uniqueness of $\{A, B\}$ for any observable B. All that is needed are Green's functions for linearized general relativity, so that the advanced $(-)$ and retarded $(+)$ perturbations of the metric $\delta_A^{\pm} g$ can be expressed as[19]

$$\delta_A^{\pm} g_{\sigma\tau}(y) = -16\pi G \int \alpha^{\mu\nu}(x) G^{\pm}_{\mu\nu\,\sigma\tau}(x, y) \sqrt{-g}\, d^4x, \tag{9}$$

where G^- and G^+ are respectively the advanced and the retarded Green's functions for the linearized Einstein equation in the gauge used. In terms of these Green's functions the Peierls bracket is

$$\{A, B\} = 16\pi G \int \alpha^{\mu\nu}(x) \Delta_{\mu\nu\,\sigma\tau}(x, y) \beta^{\sigma\tau}(y) \sqrt{-g}\, d^4x\, \sqrt{-g}\, d^4y, \tag{10}$$

with $\Delta = G^+ - G^-$ and $\beta_{\mu\nu} = \frac{1}{\sqrt{-g}} \frac{\delta B}{\delta g^{\mu\nu}}$ the functional gradient of B. Note that (10) not only provides a quite explicit definition of the Peierls bracket, but also allows the bracket to be extended to a much wider class of functionals than our observables.

To define the desired Green's function it is necessary to fix the freedom to change solutions to (6) by linearized diffeomorphisms, $\delta_A g_{\mu\nu} \to \delta_A g_{\mu\nu} + 2\nabla_{(\mu}\xi_{\nu)}$. We shall adopt the "transverse gauge" in which it is required that the trace reverse, $\bar{\gamma}_{\mu\nu} = \gamma_{\mu\nu} - \frac{1}{2} g_{\mu\nu}(g^{\sigma\rho}\gamma_{\sigma\rho})$, of the perturbation $\gamma_{\mu\nu} = \delta g_{\mu\nu}$ of the metric satisfies the condition

$$\chi_\nu \equiv \nabla^\mu \bar{\gamma}_{\mu\nu} = 0. \tag{11}$$

The linearized Einstein tensor may be written as

$$\delta G_{\mu\nu} = \nabla_{(\mu}\chi_{\nu)} - 1/2 g_{\mu\nu} \nabla_\sigma \chi^\sigma - 1/2(\nabla^\sigma \nabla_\sigma \bar{\gamma}_{\mu\nu} - 2R^\sigma{}_{\mu\nu}{}^\tau \bar{\gamma}_{\sigma\tau}), \tag{12}$$

so if (11) holds for $\delta_A g$ then (6) is equivalent to the linear, diagonal, second order hyperbolic system

$$\nabla^\sigma \nabla_\sigma \bar{\gamma}_{\mu\nu} - 2R^\sigma{}_{\mu\nu}{}^\rho \bar{\gamma}_{\sigma\rho} = 32\pi G \alpha_{\mu\nu} \tag{13}$$

(see [Wald84] section 7.5.) This equation defines unique advanced and retarded Green's functions [CDD82], with which one may calculate the unique advanced and retarded solutions, $\bar{\gamma}^{\pm}$, to (13). Moreover, these Green's functions are regular in the sense that the solutions obtained by integrating them against a C^∞ source distribution α are also C^∞.

To show that the $\bar{\gamma}^{\pm}$ correspond to solutions of the linearized Einstein equations (6) it is sufficient to show that they satisfy the transverse gauge condition. Taking the

[19] As already noted $-2\lambda\alpha$ acts as a stress energy tensor generating the perturbation of the metric. The first order (in λ) expression given in (9) for the retarded perturbation should be compared with formulae for the gravitational radiation produced by a given stress energy. (see for example [Wald84]).

divergence of (13) and using the Bianchi identity and the fact that the unperturbed metric $g_{\mu\nu}$ satisfies Einstein's vacuum field equation one obtains

$$\nabla^\sigma \nabla_\sigma \nabla^\mu \bar{\gamma}_{\mu\nu} = 32\pi G \nabla^\mu \alpha_{\mu\nu}, \tag{14}$$

a linear, diagonal, second order hyperbolic system for $\nabla^\mu \bar{\gamma}_{\mu\nu}$, with the divergence of α as the source. Since this source term vanishes, because A is diffeomorphism invariant, and $\bar{\gamma}^\pm$ vanishes either to the past or to the future of the support of α, $\nabla^\mu \bar{\gamma}^\pm_{\mu\nu} = 0$ everywhere. The corresponding metric perturbations, $\delta^\pm_A g_{\mu\nu} = \bar{\gamma}^\pm_{\mu\nu} - 1/2 g_{\mu\nu} g^{\sigma\tau} \bar{\gamma}^\pm_{\sigma\tau}$, which may be expressed in the form (9), thus *are* transverse gauge solutions to the linearized Einstein equations with source α, (6). They may therefore be used to evaluate the variations $\delta^\pm_A B$ of B.

Any variation of the metric may be transformed to one satisfying the transverse gauge condition by a suitable linearized diffeomorphism - see [Wald84]. The unicity of the advanced and retarded solutions to (13) therefore implies that all retarded and advanced perturbations satisfying (6) are equal, modulo a linearized diffeomorphism, to $\delta^+_A g_{\mu\nu}$ and $\delta^-_A g_{\mu\nu}$ respectively. Since B is diffeomorphism invariant, they all define the same variations of B, $\delta^\pm_A B$, as these. $\{A, B\}$ is thus well defined and unique.

The difficulty in applying Peierls' definition of the bracket directly to null initial data can now be understood. The basic problem is that the Green's functions $G^\pm(p, q)$ and $\Delta(p, q)$ are discontinuous in q on the light cone of p (the boundary of the causal domain of influence $J^+[p] \cup J^-[p]$ of p in M). On a flat spacetime G^+ and G^- are distributions supported entirely on the light cone itself. On curved spacetimes additional contributions should appear that are smooth functions on the interior of $J^+[p]$ but discontinuous on the boundary.[20]

This means that the Peierls bracket (10) between null initial data is ambiguous: As will be evident from the definitions of our initial data, the domain of sensitivity of an initial datum associated with a point $p \in \mathcal{N}$ consists of (a portion of) the generator, or generators, through p. The Peierls brackets between initial data at causally related points of $\mathcal{N}$, which necessarily lie on the same generator (by prop. B.7 in appendix B), is thus ambiguous because the integral (10) is ambiguous in this case. It would be interesting to find out whether the bracket on null initial data found in the present work can be obtained from a simple disambiguation of (10).

[20] The retarded Green's function in curved spacetime for the massless Klein-Gordon equation, which is very similar to the transverse gauge linearized Einstein equation, can be estimated in the limit in which the two points, p and q, are close using an adiabatic expansion (see Birrel and Davies [BD82] p. 74). In normal coordinates about p the zero order term is the Minkowski spacetime Green's function, and the lowest order correction (in a vacuum Einstein spacetime) is

$$\frac{1}{1440\pi} R^{\lambda\rho\kappa}{}_\mu R_{\lambda\rho\kappa\nu} (q-p)^\mu (q-p)^\nu \theta(p, q), \tag{15}$$

where $\theta(p, q)$ is $+1$ when q is in the causal future of p, and zero otherwise.

2.2 The Peierls bracket, the presymplectic 2-form, and the bracket on initial data

We have defined the Peierls bracket between observables, our aim is now to find a bracket $\{\cdot,\cdot\}_*$ on the null initial data which reproduces the Peierls bracket on observables when these are expressed in terms of this data. In the following I will show that the definition (7, 8) of the Peierls bracket in terms of first order perturbations governed by equation (6) implies that it is, in a certain sense, inverse to the presymplectic 2-form on the space L_g of solutions to the linearized field equations, an object which can be computed explicitly in terms of initial data from the action. We shall see, moreover, that to ensure that the bracket on the initial data on $\mathcal{N}$ reproduces the Peierls bracket on observables it is sufficient that this bracket is also inverse (in a slightly different sense) to the same presymplectic 2-form. This condition will be used in section 5 to calculate the bracket on initial data.

2.2.1 The Peierls bracket and the presymplectic 2-form

The relation between the Peierls bracket and the presymplectic 2-form is valid for any local, Lagrangean field theory - that is, for any theory derived from an action which is the spacetime integral of a Lagrangean density which is a function, at each point, only of the fields and their derivatives up to a finite order (see [LW90] for a precise definition of this class of theories). The specific features of general relativity are therefore not needed in the demonstration of this relation, and a notation which pushes these features into the background will be adopted. The key result, equation (33), may also obtained less abstractly working with the explicit form of the linearized Einstein equations, as is shown in appendix C, where (33) is obtained from a Kirchhoff type formula for the solution to the linearized field equations in terms of initial data.

Our first step will be to demonstrate a relation between variations of an observable A and the perturbation Δ_A produced by that observable. Specifically it will be shown that the contraction of Δ_A[21] with the presymplectic 2-form is equal to the gradient of A when both are pulled back to the space L_g of perturbations about a solution g which satisfy the linearized field equations.[22]

We shall work with the action on a domain Q bounded to the past by $\mathcal{N}$ and to the future by a smooth closed Cauchy surface Σ_+[23] of $\mathcal{D}$, the interior of which is contained

[21] Like any smooth variation of the metric field, Δ_A can be regarded as a tangent vector to $\mathcal{F}$.

[22] What this says is essentially that Δ_A is (minus) the Hamiltonian vector field, v_A generated by the Hamiltonian A and the presymplectic 2-form Ω. In general v_A is defined by the condition that $\delta A = -\Omega[v_A, \delta]$ $\forall \delta$ tangent to the phase space.

[23] Cauchy surfaces are defined in appendix A. The existence of Cauchy surfaces of $\mathcal{D}$ is guaranteed by the global hyperbolicity of $\mathcal{D}$ (prop. A.4 or [HE73] prop. 6.6.3.) and Geroch's theorem, prop. 6.6.8. of [HE73]. That these may be taken to be smooth follows from the result of [BS03].

in $\mathcal{D}$. Specifically Q is the closure in M of the open set $I^+[\mathcal{N}] \cap I^-[\Sigma_+] \subset \mathcal{D}$.[24] Σ_+ is chosen to lie to the future of the domain of sensitivity, s_A, of A so that s_A is contained in the interior of Q. (See Fig. 2.2.1.)

By prop. B.15 Σ_+ is compact, so prop. 6.6.1 of [HE73] and its corollary imply that, in the globally hyperbolic spacetime M, $J^+[\mathcal{N}] \cap J^-[\Sigma_+] = \overline{I^+[\mathcal{N}]} \cap \overline{I^-[\Sigma_+]} \supset Q$ is compact. Since Q is closed it is also compact. Integrals over Q are therefore defined and the Stokes theorem applies to Q and ∂Q.

$\mathcal{N}$ and Σ_+ form the entire boundary of Q in M: Suppose $p \in Q$, then, since Q is the closure of a subset of $\mathcal{D}$, $p \in \overline{\mathcal{D}}$. Since $\mathcal{D} \equiv intD[\mathcal{N}] = intD[\Sigma_+]$ [HE73] prop. 6.5.1 requires that every inextendible timelike curve γ through p crosses both $\mathcal{N}$ and Σ_+. γ must cross $\mathcal{N}$ at p or at a point r to the past of p, because $Q \subset \overline{I^+[\mathcal{N}]}$ which is disjoint from $I^-[\mathcal{N}]$ since $\mathcal{N}$ is achronal, and similarly γ must cross Σ_+ at p or at a point s to the future of p. Thus if p does not lie in either $\mathcal{N}$ or Σ_+ then $p \in I^+(r) \cap I^-(s)$, and therefore p lies in the interior of Q. (This is of course consistent with prop. B.15 which shows that $\partial\Sigma_+ = \partial\mathcal{N}$.)

For later convenience Σ_+ and $\mathcal{N}$ will *both* be oriented with the positive side to the future.[25] Thus, as oriented manifolds, $\partial Q = \Sigma_+ \cup -\mathcal{N}$ and $\partial\Sigma_+ = \partial\mathcal{N}$.

At an exact stationary point of the modified action $I + \lambda A$ the variation of this action is a boundary term:[26]

$$\delta I + \lambda \delta A = \phi[\delta], \tag{16}$$

where ϕ is the integral of a local functional of the fields and their variations over the boundary of Q.[27]

[24] The chronological past, $I^-[S]$, and future, $I^+[S]$, of a subset S of spacetime are defined in appendix A.

[25] The space of n-forms at a point of an n dimensional manifold is one dimensional. Thus there are two equivalence classes of such n-forms under multiplication by positive real numbers. The orientation of a manifold is a continuous choice of one of these equivalence classes as the "positive" one. A vector transverse to an $n-1$ dimensional submanifold emerges on the "positive side" of the submanifold if the contraction of the vector with a positive n-form is a positive $(n-1)$-form of the submanifold.

[26] By a stationary point of an action we shall always mean a field configuration at which the action is stationary with respect to all variations *that vanish in a neighbourhood of the boundary*. That is, we mean a solution to the field equations corresponding to the action.

[27] We will always take the view that δ represents the derivative along an unspecified one parameter family of field configurations, and is thus a vector in the tangent space to the space of fields being considered. Another point of view, adopted in [CW87], is that δ is the exterior derivative operator on the space of fields, and it's contraction with a vector is the derivative along the vector. Though this second point of view is not adopted in the discussion (and we denote the exterior derivative operator on the space of fields by $\mathbb{d}$) our formulae, with slight modifications, may be interpreted in this way, if one takes δ without subscripts (and $\mathbb{d}$) to be the exterior derivative, and δs with subscripts to be directional derivatives along vector fields.

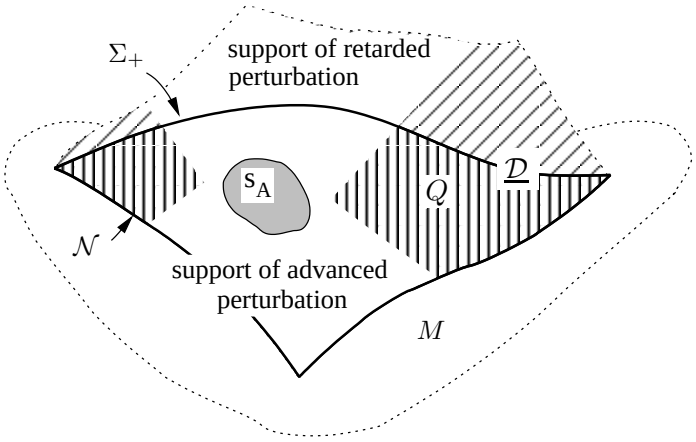

Figure 4: The diagram shows schematically (or literally in $1+1$ dimensional spacetime) the initial data hypersurface $\mathcal{N}$, its maximal Cauchy development (minus future Cauchy horizon) $\underline{\mathcal{D}}$, a boundaryless manifold M containing $\underline{\mathcal{D}}$ and $\mathcal{N}$, a Cauchy surface Σ_+ of the interior of $\underline{\mathcal{D}}$, the domain Q between $\mathcal{N}$ and Σ_+, and the domain of sensitivity s_A of an observable A. The support in $\underline{\mathcal{D}}$ of the retarded and advanced perturbations of the metric generated by A are also indicated - as white regions where the vertical or diagonal hatching is absent.

As we have seen already, whether or not exact stationary points of $I + \lambda A$ exist, approximate stationary points where the action $I + \lambda A$ is stationary up to first order in λ can be constructed by adding to any exact stationary metric g of the unperturbed action I a suitable correction $\lambda \delta_A g$ linear in λ: At the perturbed metric $g + \lambda \delta_A g$,

$$\delta I + \lambda \delta A = \phi[\delta] + O(\lambda^{1+}), \tag{17}$$

where $O(\lambda^{1+})$ vanishes faster than λ as $\lambda \to 0$.

Note that A does not contribute to ϕ, because its domain of sensitivity s_A does not intersect the boundary of Q, and consequently ϕ is independent of λ. When I is the Einstein-Hilbert action (2) on Q:

$$\phi[\delta] = -\frac{1}{8\pi G} \int_Q [\nabla_{[\mu} \delta\Gamma^{\sigma}_{\sigma]\nu} g^{\mu\nu}] \sqrt{-g}\, d^4x \tag{18}$$

$$= -\frac{1}{8\pi G} \int_{\partial Q} \delta\Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu} \sqrt{-g}\, d\Sigma_\mu, \tag{19}$$

where ∇ is the metric compatible covariant derivative, Γ is the Christoffel symbol, and $d\Sigma_\mu = 1/3!\, \epsilon_{\mu\nu\rho\tau}\, dx^\nu \wedge dx^\rho \wedge dx^\tau$ is the coordinate volume 3-form on ∂Q.[28]

The linearized field equation that governs $\delta_A g$ is obtained by differentiating (17) with respect to λ and setting $\lambda = 0$. Note that the derivative receives contributions both from the explicit λ dependence in (17) and from the λ dependence of the metric $g + \lambda \delta_A g$. The result is

$$\delta_A \delta I + \delta A = \delta_A \phi[\delta], \tag{22}$$

where, as in (6), δ_A acting on a functional of the metric is the linear variation of the functional due to the variation $\delta_A g$ in the metric.[29] The contribution from the term $O(\lambda^{1+})$ vanishes because $dO(\lambda^{1+})/d\lambda|_{\lambda=0} = \lim_{\lambda \to 0} O(\lambda^{1+})/\lambda = 0$.

[28]The exterior, or wedge, product of a sequence of forms, of valence n_1, n_2, ... adding up to a total valence of n, is defined to be $n!/(n_1!n_2!...)$ times the antisymmetric component of their tensor product. For example if a is a 1-form and b a 2-form, then

$$[a \wedge b]_{\mu\nu\sigma} = 3\, a_{[\mu} b_{\nu\sigma]}. \tag{20}$$

The integral of an n-form α over an n-manifold X is defined by

$$\int_X \alpha = \frac{1}{n!} \int_X \epsilon^{\mu_1 \ldots \mu_n} \alpha_{\mu_1 \ldots \mu_n}\, d^n x, \tag{21}$$

with ϵ antisymmetric and $\epsilon^{12\ldots n} = 1$.

[29] Note that δ and δ_A in (22) may be viewed as vector fields on the space $\mathcal{F}_Q$ of field configurations on Q, but they may equally well be taken to be vector fields on the space $\mathcal{F}$ of field configurations on all of M since no term in (22) depends on their action on the fields outside Q. We shall take the latter point of view.

In general relativity the validity of (22) for all δ with support contained in the interior of Q is equivalent to the validity of (6) there. Of course (22) also has a boundary term, probed by δs supported on the boundary. This term provides additional information, not contained in (6), which is the focus of our present interest because, as we shall see, it determines the symplectic structure and Peierls bracket of the theory.

Perturbations $g + \tau\delta_0 g$ of g which are first order (in τ) stationary points of the *unperturbed* action I obey the same equation, but without the source term δA:

$$\delta_0 \delta I = \delta_0 \phi[\delta]. \tag{23}$$

In general relativity the bulk term of this equation corresponds to the linearized vacuum Einstein equation on the interior of Q.

Setting $\delta = \delta_0$ in (22) and $\delta = \delta_A$ in (23) one obtains

$$\begin{aligned} \delta_0 A &= \delta_A \phi[\delta_0] - \delta_A \delta_0 I & (24)\\ &= \delta_A \phi[\delta_0] - \delta_0 \phi[\delta_A] - [\delta_A, \delta_0] I & (25) \end{aligned}$$

The commutator $[\delta_A, \delta_0]$ of the two vector fields δ_A and δ_0 on $\mathcal{F}$ is again a vector field (the Lie bracket of the two), so, since g is an exact stationary point of I, $[\delta_A, \delta_0] I = \phi[[\delta_A, \delta_0]]$, and

$$\begin{aligned} \delta_0 A &= \delta_A \phi[\delta_0] - \delta_0 \phi[\delta_A] - \phi[[\delta_A, \delta_0]] & (26)\\ &= \mathrm{d}\!\!\mathrm{I} \wedge \phi[\delta_A, \delta_0]. & (27) \end{aligned}$$

Here $\mathrm{d}\!\!\mathrm{I}$ is the exterior derivative operator on $\mathcal{F}$, so the right hand side of (27) is the curl of ϕ evaluated on the pair of vector fields δ_A and δ_0.[30] Its value at g depends only on the values of these vector fields at g and not on how they vary away from g. This is because the commutator term in (27) cancels the contributions to the first two terms coming from the action of δ_A on δ_0 and *vice versa*.[31]

Now consider the case in which δ_A is the retarded perturbation δ_A^+, which vanishes outside $J^+[s_A]$ in the globally hyperbolic spacetime M. The achronality of $\mathcal{N}$ requires

[30] In general, if β is a 1-form and v_1 and v_2 are vector fields then

$$d \wedge \beta(v_1, v_2) = d_{v_1} \beta(v_2) - d_{v_2} \beta(v_1) - \beta([v_1, v_2]) \tag{28}$$

where $[v_1, v_2]$ is the Lie bracket of the vectors defined by $[v_1, v_2] = d_{v_1} v_2 - d_{v_2} v_1$ or equivalently by the requirement that it's action (on a scalar) is equal to the commutator of the actions of v_1 and v_2: $d_{[v_1, v_2]} = [d_{v_1}, d_{v_2}]$.

[31] If the reader prefers, the action of δ_A on δ_0 and the action of δ_0 on δ_A, and thus also the commutator $[\delta_A, \delta_0]$, can be set to zero by taking the variations $\delta_A g_{\mu\nu}$ and $\delta_0 g_{\mu\nu}$ to be independent of the metric on which they are evaluated, that is, by taking δ_A and δ_0 to be constant vector fields on the vector space $\mathcal{F}$.

$J^+[s_A]$ to be disjoint from $\mathcal{N}$ (otherwise a future directed timelike curve from $\mathcal{N}$ to a point in s_A and a future directed causal curve from that point to $\mathcal{N}$ could be deformed to a timelike curve from $\mathcal{N}$ to $\mathcal{N}$). Furthermore, the facts that s_A is compact and M globally hyperbolic imply that $J^+[s_A]$ is closed ([HE73] prop. 6.6.1.) so it is disjoint from an open neighbourhood of $\mathcal{N}$. The boundary integral ϕ in (27) may therefore be replaced by its restriction to Σ_+, denoted Θ_{Σ_+}. Then

$$\delta_0 A = \mathrm{d}\!\!\mathrm{I} \wedge \Theta_{\Sigma_+}[\delta_A^+, \delta_0]. \tag{29}$$

(Since ϕ is an integral of a *local* functional of the fields - see (19), its functional derivatives are local functionals of the fields, so $\mathrm{d}\!\!\mathrm{I} \wedge \phi[\delta_A^+, \delta_0]$ receives no contribution from the parts of ∂Q outside the (closed) support of δ_A^+.) In principle the restriction of the boundary integral ϕ to just the portion Σ_+ of the boundary is not unambiguous. The integrand of ϕ is defined only up to total derivatives, that integrate to zero because $\partial\partial Q = \emptyset$, but which can contribute boundary terms to Θ_{Σ_+} (see [LW90]). However, these terms do not affect (29) because δ_A^+ vanishes in a neighbourhood of $\partial\Sigma_+ = \partial\mathcal{N} \subset \mathcal{N}$.

Now, we also have - for the same reasons - that the *advanced* perturbation δ_A^- vanishes on an open neighbourhood of the future boundary Σ_+. Thus, on Σ_+, the variation δ_A^+ may be replaced by

$$\Delta_A = \delta_A^+ - \delta_A^-. \tag{30}$$

Equation (29) then becomes

$$\delta_0 A = \mathrm{d}\!\!\mathrm{I} \wedge \Theta_{\Sigma_+}[\Delta_A, \delta_0] \equiv \Omega_{\Sigma_+}[\Delta_A, \delta_0], \tag{31}$$

where Ω_{Σ_+} is the *presymplectic 2-form* on $\mathcal{F}$ associated with the hypersurface Σ_+. For any pair of variations, δ_1 and δ_2,

$$\Omega_{\Sigma_+}[\delta_1, \delta_2] = \mathrm{d}\!\!\mathrm{I} \wedge \Theta_{\Sigma_+}[\delta_1, \delta_2] = \delta_1\Theta_{\Sigma_+}[\delta_2] - \delta_2\Theta_{\Sigma_+}[\delta_1] - \Theta_{\Sigma_+}[[\delta_1, \delta_2]]. \tag{32}$$

(31) holds for any δ_0 in the space of solutions to the unperturbed linearized field equation on Q, (23). All the more so it holds for a variation $\delta_0 \in L_g$ which satisfies the linearized field equation on all of M.

Notice that the variation $\Delta_A g$ also satisfies the linearized field equation (23): Subtraction of equation (22) with $\delta_A = \delta_A^-$ from the same equation with $\delta_A = \delta_A^+$ yields $\Delta_A \delta I = \Delta_A \phi[\delta]$ for all δ, which is just (23). Indeed, since this is true also when Q is replaced by any compact subset of M with smooth boundary, $\Delta_A \in L_g$.[32]

[32] If g is linearization stable this means that Δ_A, with a suitable "diffeomorphism gauge fixing", is tangent to $\mathcal{S}$. In 29 and the following developments $\delta_A^\pm$ can be any retarded/advanced perturbation

(This last result also follows directly from (6).) Indeed, since $\Delta_A B = \{A, B\}$ for any observable B, Δ_A must be the Hamiltonian vector field of $-A$.

Thus, if $\bar{\Omega}$ is defined to be the restriction of the presymplectic 2-form Ω_{Σ_+} to L_g, then (31) implies that[33]

$$\delta A = \bar{\Omega}[\Delta_A, \delta] \quad \forall\, \delta \in L_g. \tag{33}$$

(33) is the equation we were looking for. It is the key equation relating the Peierls bracket (defined by Δ_A) to the presymplectic 2-form.

(33) determines Δ_A up to degeneracy vectors of $\bar{\Omega}$, that is, up to vectors γ such that[34]

$$\bar{\Omega}[\gamma, \delta] = 0 \quad \forall\, \delta \in L_g. \tag{34}$$

This is sufficient to determine uniquely the Peierls bracket, $\{B, A\} = \Delta_B A$, of A with any observable B with domain of sensitivity contained in Q: (33) holds for any $\delta \in L_g$. It therefore holds in particular when $\delta = \Delta_B$. Thus

$$\{B, A\} = \Delta_B A = \bar{\Omega}[\Delta_A, \Delta_B]. \tag{35}$$

Clearly the right side of this equation is unaffected by the addition of degeneracy vectors of $\bar{\Omega}$ to Δ_A and Δ_B.

$\bar{\Omega}$ need not be defined using Σ_+. One obtains the same 2-form on L_g if one defines it using $\mathcal{N}$ in place of Σ_+.

Proof: $\phi = \Theta_{\Sigma_+} - \Theta_{\mathcal{N}}$. Thus, if δ_1 and δ_2 belong to L_g, then[35]

$$\begin{aligned} \bar{\Omega}_{\Sigma_+}[\delta_1, \delta_2] - \bar{\Omega}_{\mathcal{N}}[\delta_1, \delta_2] &= \delta_1\phi[\delta_2] - \delta_2\phi[\delta_1] - \phi[[\delta_1, \delta_2]] & (36)\\ &= \delta_1\delta_2 I - \delta_2\delta_1 I - [\delta_1, \delta_2]I = 0 \ \blacksquare. & (37) \end{aligned}$$

Actually, since $\Theta_{\Sigma_+}[\delta]$ does not depend on the shape of the remainder, $\partial Q - \Sigma_+$, of the boundary of Q, any piecewise differentiable hypersurface Σ which together with Σ_+ encloses a compact spacetime region on which Einstein's field equations hold can be used instead of $\mathcal{N}$ or Σ_+ to evaluate $\bar{\Omega}[\delta_1, \delta_2]$, and gives the same result. In particular

---

to the metric generated by A (i.e. by the source $16\pi G\alpha$ in the linearized field equation). It need not satisfy any further restriction, such as the transverse gauge condition, and so neither does Δ_A. Diffeomorphism generators with support contained in the causal domain of influence of s_A may be freely added to Δ_A. If this freedom is exploited to ensure that Δ_A, viewed as a perturbation of the metric, does not move the boundaries of the domain of dependence of $\mathcal{N}$ in M then it is tangent to $\mathcal{S}$ provided g is linearization stable.

[33] Restricting δ_0 in (31) to lie in L_g implies no loss of generality since any solution of the linearized field equations on Q can be extended to a solution on all of M.

[34] In fact the ambiguity in Δ_A is further restricted by the definitions of δ_A^+ and δ_A^-, which require that Δ_A vanishes outside of the causal domains of influence $J^+[s_A]$ and $J^-[s_A]$ of s_A.

[35] Recall that the commutator of the actions, as derivative operators, of two vector fields is equal to the action of their Lie bracket, which is itself a vector field.

any smooth Cauchy surface of $\mathcal{D}$ will do. [This does not exhaust the possibilities. In principle the hypersurface need not even be achronal, or contained in $\overline{\mathcal{D}}$. On the other hand our proof only guarantees the validity of (33) if $s_A \subset \mathcal{D}$.]

From (19) one immediately obtains Ω for the Einstein-Hilbert action:

$$\begin{aligned} \Omega_\Sigma[\delta_1, \delta_2] &= \delta_1\Theta_\Sigma[\delta_2] - \delta_2\Theta_\Sigma[\delta_1] - \Theta_\Sigma[[\delta_1, \delta_2]] && (38) \\ &= -\frac{1}{8\pi G}\int_\Sigma \delta_2\Gamma^{[\sigma}_{\sigma\nu}\delta_1[g^{\mu]\nu}\sqrt{-g}]d\Sigma_\mu - (1 \leftrightarrow 2) && (39) \end{aligned}$$

This agrees (up to an over all factor) with the expression proposed by Crnkovic and Witten [CW87]. Moreover, when Σ is spacelike (39) reduces to the standard expression in terms of ADM variables [ADM62][LW90]: In Gaussian normal coordinates r^α based on Σ $r^0 = 0$ on Σ and $\partial/\partial r^0$ is the unit future directed tangent to the congruence of geodesics normal to Σ. Consequently $g^{00} = g_{00} = -1$, $g^{0i} = g_{0i} = 0$, and $g_{ij} = h_{ij}$ where indices $i, j, k, ...$ range over $\{1, 2, 3\}$ and h is the induced 3-metric on Σ. Moreover $\Gamma^0_{00} = \Gamma^i_{00} = 0$ and $\Gamma^0_{ij} = K_{ij}$, $\Gamma^i_{j0} = h^{ik}K_{kj}$ where $K_{ij} = 1/2\,\partial_0 h_{ij}$ is the extrinsic curvature of Σ. The presymplectic 2-form is thus

$$\Omega_\Sigma[\delta_1, \delta_2] = \frac{1}{16\pi G}\int_\Sigma \delta_2 K\delta_1\sqrt{h} + \delta_2 K_{ij}\delta_1[h^{ij}\sqrt{h}]d^3r - (1 \leftrightarrow 2), \qquad (40)$$

where $K = K_{ij}h^{ij}$ and $h = det[h_{ij}]$. In terms of h_{ij} and the ADM momentum variable[36]

$$\pi^{ij} = \sqrt{h}[K^{ij} - Kh^{ij}]/16\pi G \qquad (41)$$

the presymplectic 2-form becomes

$$\Omega_\Sigma[\delta_1, \delta_2] = \int_\Sigma \delta_1\pi^{ij}\delta_2 h_{ij}d^3r - (1 \leftrightarrow 2). \qquad (42)$$

2.2.2 The Peierls bracket is a Poisson bracket

(35) allows us to verify that the Peierls bracket $\{\cdot, \cdot\}$ really is a Poisson bracket on the observables. In order that $\{\cdot, \cdot\}$ be a Poisson bracket it must [Mar92]

i be skew symmetric,

ii be linear in each argument (under addition and multiplication by a constant),

iii satisfy the Leibniz rule $\{A, BC\} = \{A, B\}C + B\{A, C\}$,

and

[36] The normalization of π corresponds to the normalization of the action (2) used here.

iv satisfy the Jacobi relation,

$$\{A,\{B,C\}\}+\{B,\{C,A\}\}+\{C,\{A,B\}\}=0 \tag{43}$$

(35) immediately shows that i, ii and iii are satisfied. The last requirement, the Jacobi relation, follows from the fact that Ω, being the curl of Θ, is itself a closed 2-form. For any 2-form α and triplet of vector fields u,v,w

$$\underset{\mathrm{u,v,w}}{\mathrm{Cyc}}\; d_u\alpha(v,w)=d\wedge\alpha(u,v,w)+\underset{\mathrm{u,v,w}}{\mathrm{Cyc}}\;\alpha([u,v],w) \tag{44}$$

(where $\underset{\mathrm{u,v,w}}{\mathrm{Cyc}}$ denotes the sum over cyclic permutations of the sequence u,v,w). From (35), (44) and the fact that $d\mathbb{I}\wedge\Omega=0$ it follows that[37]

$$X\equiv\underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;\{A,\{B,C\}\}=-\underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;\Delta_A\bar{\Omega}[\Delta_B,\Delta_C]=-\underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;\bar{\Omega}[[\Delta_A,\Delta_B],\Delta_C] \tag{47}$$

and therefore

$$\begin{aligned} X &= \underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;[\Delta_A,\Delta_B]C=\underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;\{A,\{B,C\}\}-\{B,\{A,C\}\} && (48)\\ &= \underset{\mathrm{A,B,C}}{\mathrm{Cyc}}\;(X-\{C,\{A,B\}\})=3X-X=2X && (49)\end{aligned}$$

Thus $X=0$, which is precisely the Jacobi relation (43).

2.2.3 Definition of the bracket on initial data

We turn now to the problem of defining a bracket on the initial data on $\mathcal{N}$, to be called the *auxiliary bracket* and denoted by $\{\cdot,\cdot\}_*$, which reproduces the Peierls bracket on observables when these are expressed in terms of the initial data.

A skew symmetric bracket, $\{\varphi_I,\varphi_J\}_*$, defined on all pairs φ_I, φ_J of initial data determine a bracket

$$\{F,G\}_*=\sum_{I,J}\frac{\partial F}{\partial\varphi_I}\{\varphi_I,\varphi_J\}_*\frac{\partial G}{\partial\varphi_J}. \tag{50}$$

[37] Actually it is not necessary to invoke a differentiable structure on $\mathcal{F}$ to obtain the Jacobi relation. The crucial relation

$$\underset{\mathrm{1,2,3}}{\mathrm{Cyc}}\;\delta_1\bar{\Omega}[\delta_2,\delta_3]=\underset{\mathrm{1,2,3}}{\mathrm{Cyc}}\;\bar{\Omega}[[\delta_1,\delta_2],\delta_3], \tag{45}$$

that we have obtained from (44) and $d\mathbb{I}\wedge\Omega=0$, follows algebraically from (32) -

$$\bar{\Omega}[\delta_1,\delta_2]=\delta_1\Theta_{\Sigma_+}[\delta_2]-\delta_2\Theta_{\Sigma_+}[\delta_1]-\Theta_{\Sigma_+}[[\delta_1,\delta_2]]\quad\forall\delta_1,\delta_2\in L_g. \tag{46}$$

on all pairs F, G of differentiable functions of the initial data. Here the indices I, J comprehend all continuous and discrete labels of the initial data components (including position in $\mathcal{N}$), $\sum_{I,J}$ represents the integral and/or sum over the set of such labels and $\partial/\partial\varphi_I$ represents ordinary partial differentiation or functional differentiation as appropriate. $\{\cdot,\cdot\}_*$ as defined by (50) is skew symmetric, linear in its arguments, and satisfies the Leibniz rule. This makes it a *pre-Poisson* bracket - a Poisson bracket save that it may not satisfy the Jacobi relation.

This bracket is defined on observables only if they are differentiable functionals of the initial data. That they are can be demonstrated if it is assumed, as we have done elsewhere, that Rendall's [Ren90] results on the Cauchy development of null initial data apply to all of $\mathcal{N}$, and not just to a neighbourhood of S_0 in $\mathcal{N}$. Rendall shows that in the Cauchy developments corresponding to a differentiable one parameter family of Sachs initial data the metric at a given harmonic coordinate point is also differentiable in the family parameter. The same is then easily seen to be the case for the closely related initial data we shall use (defined in subsection 3.3).

The derivative, $\delta g_{\mu\nu}$, of the metric field in the family parameter is a solution to the linearized field equation, so the corresponding derivative of an observable A satisfies $\delta A = \Omega_{\mathcal{N}}[\Delta_A, \delta]$. The linear operator $\Omega_{\mathcal{N}}[\Delta_A, \cdot]$ is a distribution on the derivative $\delta\varphi_I$ of the initial data. Indeed it can be seen at once from the explicit form (195) of $\Omega_{\mathcal{N}}$ in terms of our initial data, and the smoothness of Δ_A, that $\Omega_{\mathcal{N}}[\Delta_A, \cdot]$ is a regular distribution, equivalent to integration of the variations of the initial data against smooth functions. Since $\Omega_{\mathcal{N}}[\Delta_A, \cdot]$ depends only on the definition of A and on the unperturbed metric, and not on which one parameter family of initial data is being considered, it is in fact the functional derivative of A by the initial data. $\partial A/\partial\varphi_I$ thus exists and is a smooth function of the the continuous position label in the index I.

Note that Δ_A vanishes in a spacetime neighbourhood of $\partial\mathcal{N}$ (because both δ_A^- and δ_A^+ do so). We will take care in the definition of our initial data to make sure that variations of the metric that vanish near $\partial\mathcal{N}$ also leave the initial data undisturbed near $\partial\mathcal{N}$, so $\Delta_A\varphi_I = 0$ for data in some neighbourhood of $\partial\mathcal{N}$. Since $\Omega_{\mathcal{N}}[\Delta_A, \delta]$ is an integral over the initial data and their variations under Δ_A and δ on $\mathcal{N}$ (see (195)) the variations $\delta\varphi_I$ corresponding to points sufficiently close to $\partial\mathcal{N}$ will not contribute. That is, the derivative $\partial A/\partial\varphi_I$ vanishes for I corresponding to points in a neighbourhood of $\partial\mathcal{N}$.

A sufficient condition ensuring that $\{\cdot,\cdot\}_*$ reproduces the Peierls bracket on observables is that the motion $\{A, \cdot\}_*$ generated by any observable A via the bracket

satisfies[38]

$$\delta A = \bar{\Omega}[\{A, \cdot\}_*, \delta] \quad \forall\, \delta \in L_g^0, \tag{51}$$

where L_g^0 is the space of variations satisfying the linearized field equations and the requirement that $\delta g_{\mu\nu}$ vanishes in some neighbourhood of $\partial\mathcal{N}$ in M. Then

$$\{A, B\} = \Delta_A B = \bar{\Omega}[\{B, \cdot\}_*, \Delta_A] = -\bar{\Omega}[\Delta_A, \{B, \cdot\}_*] = -\{B, A\}_* = \{A, B\}_*. \tag{52}$$

for all observables A and B. The first equality is just the definition of the Peierls bracket; the second follows from (51), using the fact that Δ_A vanishes in a neighbourhood of $\partial\mathcal{N}$; the third from the antisymmetry of $\bar{\Omega}$; the fourth from (33); and the last from the assumed antisymmetry of $\{\cdot, \cdot\}_*$.

Condition (51) is satisfied if

$$\delta\varphi_I = \Omega_{\mathcal{N}}[\{\varphi_I, \cdot\}_*, \delta] \quad \forall\, \delta \in L_g^0 \tag{53}$$

for all initial data φ_I living on the interior of $\mathcal{N}$. Indeed it is sufficient that (53) holds when both sides are integrated against smooth functions that vanish in a neighbourhood of $\partial\mathcal{N}$, for (51) is obtained from (53) by contracting both sides of (53) with $\partial A/\partial\varphi_I$.

(53) even implies that $\{A, \cdot\}_* = \Delta_A$ distributionally on initial data on the interior of $\mathcal{N}$. If θ is initial data smeared with a smooth function supported in $int\mathcal{N}$ then $\{\theta, \cdot\}_*$, like $\{A, \cdot\}_*$, corresponds to an element of L_g. One may therefore repeat the arguments of equation (52), from the second equality on, with θ in place of B, and conclude that $\Delta_A\theta = \{A, \theta\}_*$. (This result also follows from (353) and (53).)

Notice that both (51) and (53), by ensuring that $\{\cdot, \cdot\}_*$ reproduces the Peierls bracket on observables, also ensure that the Jacobi relation holds for $\{\cdot, \cdot\}_*$ on observables. Nevertheless neither (51) nor (53) imply that the Jacobi relation holds for brackets between arbitrary functions of the data.[39] Indeed the bracket solving (51) that we find does not satisfy the Jacobi relation. As long as one is only interested in reproducing the Peierls Poisson algebra of the observables the validity of the Jacobi relation for brackets of the initial data is evidently not necessary, but if one wishes to quantize the system by replacing these brackets by commutators this relation becomes indispensable, since it holds identically for commutators.

[38] $\{A, \cdot\}_*$ is a variation of the initial data. That it necessarily corresponds to a solution to the linearized Einstein equation of course follows from the extensions of Rendall's results [Ren90] that we have assumed, but it can also be seen directly from the explicit formula for the solution (367) obtained in appendix C.

[39] One might think that the Jacobi relation follows from (53), which essentially requires that $\{\cdot, \cdot\}_*$ be inverse to $\bar{\Omega}$. As we saw in sub-subsection 2.2.2, the analogous condition (33) does imply the Jacobi relation for the Peierls bracket between observables. However (53) applies only to variations δ vanishing in some neighbourhood of $\partial\mathcal{N}$, so $\{\cdot, \cdot\}_*$ is only almost inverse to $\bar{\Omega}$, which turns out not to be sufficient.

Our task will therefore be to find a skew symmetric bracket on initial data, $\{\varphi_I, \varphi_J\}_*$, satisfying (53). Two further conditions will be imposed on this bracket. The first of these relates to constraints. We shall calculate the bracket on a set of initial data which are almost, but not entirely, free. They are subject to one constraint at the intersection 2-surface S_0 of the two null branches of $\mathcal{N}$. The brackets on these almost free data then allow us to evaluate the brackets of a second set of data, which are completely free. As is always the case for constrained data the bracket on the almost free data defines an equivalent bracket on the completely free data iff it respects the constraints. That is to say, we must require that the functions of the data that are constrained to vanish also have vanishing brackets with all data.

The second, and last, condition is a requirement of causality. We require that the auxiliary bracket vanishes between data at points of $\mathcal{N}$ that are not connected by a causal curve. Since disjoint generators are not connected by causal curves (prop. B.7) it follows that the only non-zero brackets are those between data on the same generator, which facilitates considerably our calculations.

Whether the causality requirement is independent of (53) or implicit in it is unclear at present. The causality requirement seems quite reasonable in view of the causality property of the Peierls bracket - namely that the Peierls bracket between observables with domains of sensitivity unconnected by any causal curve vanishes. As will be clear from the definitions of our data, the domain of sensitivity of a datum at a point $p \in \mathcal{N}$, as a functional of the spacetime metric,[40] is contained in the generator through p, or the pair of generators through p in the case that $p \in S_0$. Thus the Peierls bracket between data on distinct generators, if it can be defined, should vanish. Indeed this can be done. (10) allows us to define the Peierls bracket between initial data that do not live on the same generator, provided a suitable fixing of the diffeomorphism freedom in the data and the Green's functions is adopted, and this Peierls bracket must vanish because the advanced and retarded Green's functions that enter (10) vanish between points that cannot be connected by causal curves. That the causality requirement is at least compatible with the other requirements follows *a posteriori* from the fact that a bracket satisfying all the requirements is found.

2.2.4 Degeneracy vectors of the presymplectic 2-form and the consistency of the definition of the auxiliary pre-Poisson bracket

The consistency of (53) will be fully established *post hoc* by the fact that a solution to this condition is found. Nevertheless it is interesting to attempt to verify consistency already at this stage, before entering into the details of a particular representation of the solutions (i.e. of the initial data). We shall succeed in doing so in the generic

[40] Quite generally the domain of sensitivity of a functional F of the metric will be defined to be the support in spacetime of its functional gradient $\delta F/\delta g^{\mu\nu}$.

case in which a neighbourhood of each point can be coordinatized by scalars defined by the geometry.

The consistency of (53) requires that all data φ_I be invariant under the action of degeneracy vectors γ of $\bar{\Omega}$ such that the corresponding variation of the metric, γg, vanishes in a spacetime neighbourhood of $\partial\mathcal{N}$. At least on generic solutions these turn out to be diffeomorphism generators, i.e $\gamma = \pounds_\xi$ for some vector field ξ on $\underline{\mathcal{D}}$.[41] In fact the following stronger result holds

Proposition 2.1 *In the generic case, in which there exist at each point of $\underline{\mathcal{D}}$ four smooth functions of the metric g and a finite number of its derivatives, having smooth, linearly independent spacetime gradients, any variation $\gamma \in L_g$ that satisfies the generalized degeneracy condition*

$$\bar{\Omega}(\gamma, \delta) = 0 \quad \forall \delta \in L_g^0 \tag{54}$$

is a diffeomorphism generator on $\underline{\mathcal{D}}$.

Proof: Any divergenceless, C^∞, symmetric, bivalent tensor field α of compact support contained in $\mathcal{D}$ defines, via (8) and (9) a vector $\Delta_A \in L_g^0$ which, by (33), must satisfy

$$\int \delta g_{\mu\nu}\, \alpha^{\mu\nu} \sqrt{-g}\, d^4x = \bar{\Omega}[\Delta_A, \delta] \;\; \forall\, \delta \in L_g. \tag{55}$$

If δ is a generalized degeneracy vector γ, satisfying (54) then the right side vanishes and we have

$$\int \gamma g_{\mu\nu}\, \alpha^{\mu\nu} \sqrt{-g}\, d^4x = 0 \tag{56}$$

for all α satisfying our conditions.

Let p be a point of $\underline{\mathcal{D}}$, and $z^\alpha, \alpha = 0, ..., 3$ four smooth functionals of the metric with linearly independent gradients dz^α. By the inverse function theorem these form a smooth chart on a neighbourhood U of p in $M \supset \underline{\mathcal{D}}$. The components of the metric in this chart are diffeomorphism invariant, so differentiating any functional of these components by the components of the metric in a manifold fixed chart yields a symmetric, divergenceless tensor. Generalizing this observation we shall consider linear functionals of the form

$$F[\delta g] = \int \delta g_{\alpha\beta} \bar{f}^{\alpha\beta} \sqrt{-g_z}\, d^4z \tag{57}$$

where $g_{\alpha\beta}$ are the components of the metric in the z chart and $\bar{f}^{\alpha\beta}$ is an arbitrary symmetric matrix of functions with support contained in $U \cap \mathcal{D}$. The variation of $g_{\alpha\beta}$

[41] The tangent to a one parameter family of diffeomorphisms is the Lie derivative $\pounds_\xi$ along the vector field ξ of tangents to the orbits of the manifold points.

is related to the variations of the components, $g_{\mu\nu}$, of the metric in a manifold fixed chart x by

$$\delta g_{\alpha\beta} = \frac{\partial x^\mu}{\partial z^\alpha}\frac{\partial x^\nu}{\partial z^\beta}[\delta g_{\mu\nu} - \pounds_{\xi[\delta]} g_{\mu\nu}] \tag{58}$$

where

$$\xi[\delta]^\mu(q) = \frac{\partial x^\mu}{\partial z^\alpha}(q)\int \delta g_{\nu\rho}(r)\frac{\delta z^\alpha(q)}{\delta g_{\nu\rho}(r)}\, d^4x(r) \tag{59}$$

at each $q \in U$. (q is fixed in the spacetime manifold, $z^\alpha(q)$ thus varies when the metric varies.) Thus

$$\begin{aligned} F[\delta g] &= \int [\delta g_{\mu\nu} - 2\nabla_{(\mu}\xi[\delta]_{\nu)}]\bar{f}^{\mu\nu}\sqrt{-g_x}\, d^4x & (60)\\ &= \int \{\delta g_{\mu\nu}\bar{f}^{\mu\nu} + 2\xi[\delta]^\rho g_{\rho\nu}\nabla_\mu \bar{f}^{\mu\nu}\}\sqrt{-g_x}\, d^4x & (61)\\ &= \int \delta g_{\mu\nu} f^{\mu\nu}\sqrt{-g_x}\, d^4x & (62) \end{aligned}$$

with

$$\bar{f}^{\mu\nu} = \frac{\partial x^\mu}{\partial z^\alpha}\frac{\partial x^\nu}{\partial z^\beta}\bar{f}^{\alpha\beta} \tag{63}$$

and

$$f^{\mu\nu}(r) = \bar{f}^{\mu\nu}(r) + \frac{2}{\sqrt{-g_x}}\int \frac{\delta z^\alpha}{\delta g_{\mu\nu}(r)}\frac{\partial x^\rho}{\partial z^\alpha} g_{\rho\tau}\nabla_\sigma \bar{f}^{\sigma\tau}\sqrt{-g_x}\, d^4x \tag{64}$$

This tensor is smooth because the functional derivative is a sum with smooth coefficients of derivatives, up to finite order, of delta distributions, and this distribution is convolved with a smooth function. Clearly the support of f is contained in that of $\bar{f}$, which in turn is contained in $U \cap \mathcal{D}$. Finally, f is divergenceless. This can be verified by letting $\delta = \pounds\zeta$ with ζ smooth and of compact support contained in U:

$$F[\pounds\zeta] = -\int \zeta_\nu \nabla_\mu f^{\mu\nu}\sqrt{-g_x}\, d^4x \tag{65}$$

vanishes because $\xi[\pounds\zeta] = \zeta$, since z^α are functionals of the metric only, and thus the variation of the z components of the metric vanishes. ((65) can also be verified by direct calculation.) (65) for all smooth, compactly supported ζ implies $\nabla_\mu f^{\mu\nu} = 0$.

Thus $F[\gamma] = 0$ for all $\bar{f}^{\alpha\beta}$, (which are smooth and have compact support contained in $U \cap \mathcal{D}$) which implies that

$$0 = \gamma g_{\alpha\beta} = \gamma g_{\mu\nu} + \pounds_{\xi[\gamma]} g_{\mu\nu}. \tag{66}$$

That is $\gamma = \pounds_\xi$, a diffeomorphism generator, on $U \cap \mathcal{D}$. Clearly this implies that γ is a diffeomorphism generator throughout $\mathcal{D}$.

In fact γ is a diffeomorphism generator also on $int\mathcal{N}$. By the Whitney extension theorem (see [AR67]) γg can be extended smoothly to a neighbourhood of $int\mathcal{N}$ in M. $\xi[\gamma]$ is defined on the intersection of U with this neighbourhood. Therefore, since both γ and $\pounds_{\xi[\gamma]}$ define smooth variations of the metric, $\gamma g = \pounds_{\xi[\gamma]} g$ on $U \cap int\mathcal{N}$ which is a subset of the boundary of $\mathcal{D}$ in the topology of U. ∎

The genericity assumption does not actually seem to be necessary. In particular, the result holds in a flat spacetime, which does not satisfy this assumption.

In any case, we may conclude that in the generic case that a generalized degeneracy vector is a diffeomorphism generator on $\underline{\mathcal{D}}$. Conversely, a direct calculation (which will be useful for another purpose further on)[42] shows that

Proposition 2.2 *Any diffeomorphism generator is a generalized degeneracy vector of* $\bar{\Omega}$.

Proof: Suppose ξ is a C^∞ vector field on $\underline{\mathcal{D}}$, δ is a variation satisfying the linearized vacuum field equation, and Σ is a smooth Cauchy surface of $\mathcal{D}$, contained in $\mathcal{D}$. Note that a smooth Cauchy surface exists by [BS03], and that by prop. B.15 the closure $\bar{\Sigma}$ of Σ in M is an embedded compact 3-manifold with boundary $\partial\mathcal{N}$. For the sake of simplicity (it makes no difference to the result) suppose ξ is independent of the metric, and thus $\delta\xi = 0$. Then

$$\bar{\Omega}[\pounds_\xi, \delta] = \pounds_\xi \Theta_\Sigma[\delta] - \delta\Theta_\Sigma[\pounds_\xi]. \tag{67}$$

Now

$$\Theta_\Sigma[\delta] = -\frac{1}{8\pi G}\int_\Sigma \delta\Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu}\sqrt{-g}\, d\Sigma_\mu \tag{68}$$

$$= \int_\Sigma \alpha \tag{69}$$

where α is the 3-form $-1/(3!\,8\pi G)\,\delta\Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu}\epsilon_{\mu\lambda\rho\tau}\sqrt{-g}\, dx^\lambda \wedge dx^\rho \wedge dx^\tau$. Thus

$$\pounds_\xi \Theta_\Sigma[\delta] = \int_\Sigma \pounds_\xi \alpha = \int_\Sigma \xi \lrcorner\, [d \wedge \alpha] + \int_\Sigma d \wedge [\xi \lrcorner\, \alpha]. \tag{70}$$

But $d \wedge \alpha = 1/(16\pi G)\delta R\sqrt{-g}\, dx^0 \wedge dx^1 \wedge dx^2 \wedge dx^3$, the divergence term in the variation of the Einstein-Hilbert Lagrangean density, which vanishes because $g \in \mathcal{S}$ and $\delta \in L_g$ and thus $R = \delta R = 0$. Therefore

$$\pounds_\xi \Theta_\Sigma[\delta] = \int_{\partial\bar{\Sigma}} \xi \lrcorner\, \alpha \tag{71}$$

$$= \frac{1}{8\pi G}\int_{\partial\bar{\Sigma}} \xi^\mu \delta\Gamma^{[\sigma}_{\sigma\tau} g^{\nu]\tau}\sqrt{-g}\, d\Sigma_{\mu\nu} \tag{72}$$

$$= \frac{1}{8\pi G}\int_{\partial\bar{\Sigma}} \xi^\mu (\nabla^\nu \delta\sqrt{-g} + \frac{1}{2}\nabla_\sigma \delta g^{\nu\sigma}\sqrt{-g})\, d\Sigma_{\mu\nu}. \tag{73}$$

[42] A more general argument is given in subsection 2.3.

Here $d\Sigma_{\mu\nu} = 1/2\,\epsilon_{\mu\nu\rho\tau}\,dx^\rho \wedge dx^\tau$ is the coordinate area 2-form, and in the last line the identity

$$\delta\Gamma^\sigma_{\mu\nu} = \frac{1}{2}g^{\sigma\tau}\{\nabla_\nu g_{\tau\mu} + \nabla_\mu g_{\tau\nu} - \nabla_\tau g_{\mu\nu}\}. \tag{74}$$

has been used.

The second term in (67) is the δ variation of

$$\Theta_\Sigma[\pounds_\xi] = -\frac{1}{8\pi G}\int_\Sigma \pounds_\xi \Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu}\sqrt{-g}\,d\Sigma_\mu \tag{75}$$

But (74) and Einstein's field equation, which is satisfied by g, imply that

$$\begin{aligned}
\pounds_\xi \Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu}\sqrt{-g} &= (\nabla^\mu\nabla_\sigma\xi^\sigma - \frac{1}{2}\nabla_\sigma\nabla^\sigma\xi^\mu - \frac{1}{2}\nabla_\sigma\nabla^\mu\xi^\sigma)\sqrt{-g} &(76)\\
&= \nabla_\sigma\nabla^{[\mu}\xi^{\sigma]}\sqrt{-g} &(77)\\
&= \partial_\sigma[\nabla^{[\mu}\xi^{\sigma]}\sqrt{-g}]. &(78)
\end{aligned}$$

Taking the integral one obtains

$$\Theta_\Sigma[\pounds_\xi] = -\frac{1}{16\pi G}\int_{\partial\bar{\Sigma}} \nabla^{[\mu}\xi^{\nu]}\sqrt{-g}\,d\Sigma_{\mu\nu}. \tag{79}$$

Summing (73) and minus the δ variation of (79) one obtains

$$\begin{aligned}
\bar{\Omega}[\pounds_\xi,\delta] &= \frac{1}{16\pi G}\int_{\partial\bar{\Sigma}} \xi^\mu\{2\nabla^\nu\delta\sqrt{-g} + \nabla_\sigma\delta g^{\nu\sigma}\sqrt{-g}\} + \delta\{\nabla^\mu\xi^\nu\sqrt{-g}\}d\Sigma_{\mu\nu}, &(80)\\
&= \frac{1}{16\pi G}\int_{\partial\bar{\Sigma}} 3\xi^{[\mu}\delta\Gamma^\sigma_{\sigma\tau}g^{\nu]\tau}\sqrt{-g} + \delta[\sqrt{-g}g^{\sigma\mu}]\nabla_\sigma\xi^\nu d\Sigma_{\mu\nu}, &(81)
\end{aligned}$$

Since this is a boundary integral it certainly vanishes if δ vanishes in a neighbourhood of $\partial\bar{\Sigma} = \partial\mathcal{N}$, showing that any diffeomorphism generator is a generalized degeneracy vector of $\bar{\Omega}$. ∎

In order that $\pounds_\xi$ be a *true* degeneracy vector the boundary integral (81) must vanish for all $\delta \in L_g$. A sufficient condition is that ξ and it's gradient vanish on $\partial\Sigma$. It is not clear to the author whether this is a necessary condition.

According to prop. 2.1, when the metric g on $\underline{\mathcal{D}}$ is generic a degeneracy vector of $\bar{\Omega}$ which preserves the metric in a neighbourhood of $\partial\mathcal{N}$ is a diffeomorphism generator which vanishes in this neighbourhood. Our initial data will be invariant under all diffeomorphisms which preserve $\partial\mathcal{N}$, so they are certainly invariant under such degeneracy vectors, implying that (53) is consistent in this case.

On the other hand on any solution, even one with a non-generic metric, (53) only defines $\{\varphi_I,\cdot\}_*$ up to a generalized degeneracy vector. Thus, according to prop. 2.2,

one is free to add a diffeomorphism generator. This ambiguity is to be expected if $\{\cdot,\cdot\}_*$ is determined only by the requirement that it reproduces the Peierls bracket on observables, because observables are diffeomorphism invariant.

The consequent ambiguity of the brackets between our initial data is not very great however, because the data are invariant under a large subgroup of diffeomorphisms. Nevertheless, the freedom to add diffeomorphism generators to the solutions of (53) will be used to simplify calculations further on.

Finally, the fact that any diffeomorphism generator that vanishes in a neighbourhood of $\partial\mathcal{N}$ is a true degeneracy vector of $\bar{\Omega}$ implies that we may, without changing the consequences of (53), add a suitable diffeomorphism generator to each variation in L^0_g such that the total variation preserves the null character of the branches of $\mathcal{N}$. This partial "gauge fixing" of L^0_g, which will be adopted from here on, simplifies our subsequent considerations, principally because the fixed hypersurface $\mathcal{N}$ then carries null initial data for the varied solutions and the variation of this data is simply a function of the variation of the metric (and of its derivatives) on $\mathcal{N}$.

It is tempting to try to go further and restrict the variations so that they leave the generators of $\mathcal{N}$ fixed (i.e. the null generators for a varied solution are the same as in the fiducial solution). This *can* be done by adding suitable diffeomorphism generators $\pounds_\xi$ to the variations in L^0_g, but in general ξ cannot be chosen to vanish in a neighbourhood of $\partial\mathcal{N}$, so the resulting variation will not lie in L^0_g: Imagine following the generators back in time from the boundary $\partial\mathcal{N}$ to S_0, that is, from the disks S_L and S_R where the generators of $\mathcal{N}_L$ and $\mathcal{N}_R$, respectively, cross the boundary. (See Fig. 1). A perturbation which vanishes in a neighbourhood of $\partial\mathcal{N}$ will leave the generators fixed in that neighbourhood. However, it will in general affect which generator from S_L meets a given generator from S_R at S_0. So no diffeomorphism acting only in the interior of $\mathcal{N}$ can restore the generators to their unperturbed positions. Aside from the exceptional cases in which the the geometry near $\partial\mathcal{N}$ admits non-trivial isometries, these are the only diffeomorphisms that leave the metric invariant near $\partial\mathcal{N}$. Thus, while a perturbation of the metric that preserves the geometry near $\partial\mathcal{N}$ can always be reduced by the addition of a suitable diffeomorphism to a perturbation that vanishes (i.e. preserves the metric tensor) in a neighbourhood of $\partial\mathcal{N}$, it is not in general possible to add a diffeomorphism so that the total perturbation leaves both the metric invariant near $\partial\mathcal{N}$ *and* the generators invariant on all of $\mathcal{N}$.

We shall continue to use variations δ which vanish near $\partial\mathcal{N}$ in (53), and the generators will not in general be fixed under under these variations, even though the hypersurface $\mathcal{N}$ they collectively sweep out is.

2.2.5 The auxiliary bracket for spacelike initial data

Our conditions also serve to define a bracket on spacelike initial data, which turns out to be the same as the Poisson bracket used in the ADM formulation of canonical GR [ADM62]. This implies that the Peierls bracket between a pair of observables of the domain of dependence of a Cauchy surface Σ is equal to the bracket between these in the ADM theory. Our theory is thus equivalent to the ADM theory.

The auxiliary bracket is a solution to (53), but it is convenient to first solve the simpler, but analogous condition

$$\delta\varphi_I = \Omega_\Sigma[\{\varphi_I, \cdot\}_\Delta, \delta] \quad \forall\, \delta \text{ vanishing near } \partial\Sigma. \tag{82}$$

This condition is stronger than (53) because it must hold for all δ vanishing in a neighbourhood of the boundary, not just those satisfying the linearized field equations. On the other hand $\{\varphi_I, \cdot\}_\Delta$ will not be required to satisfy the linearized field equations either (for this reason Ω must be used instead of $\bar{\Omega}$).[43] When Σ is a spacelike Cauchy surface of $\underline{\mathcal{D}}$ one may use the ADM variables, consisting of the induced 3-metric h and the momentum variable π defined in (41), as the initial data. In terms of these variables the presymplectic 2-form is given by the simple expression (42). It follows immediately that the unique solution to (82) is the standard ADM kinematic Poisson bracket:

$$\{h_{ij}(x), \pi^{kl}(y)\}_\Delta = \delta^k_{(i}\delta^l_{j)}\delta^3(x,y) \tag{83}$$

$$\{h_{ij}(x), h_{kl}(y)\}_\Delta = \{\pi^{ij}(x), \pi^{kl}(y)\}_\Delta = 0 \tag{84}$$

for all x and y in the interior of Σ.

Now let's return to the auxiliary bracket $\{\cdot,\cdot\}_*$, which satisfies (53). (53) requires that $\delta\varphi_I = \Omega_\Sigma[\{\varphi_I, \cdot\}_*, \delta]$ holds for all δ that vanish near $\partial\Sigma$ and satisfy the linearized field equations (that is $\forall\delta \in L^0_g$). Moreover $\{\varphi_I, \cdot\}_*$ is also required to satisfy the linearized field equations. These conditions are equivalent to requiring that the actions of δ and $\{\varphi_I, \cdot\}_*$ annihilate the constraints on the data on Σ (for if a perturbation of the initial data satisfies the linearized constraints then there always exists a solution to the linearized field equations matching the perturbation).[44] If δ annihilates the

[43] $\{\cdot,\cdot\}_\Delta$ is (a generalization of) the kinematic Poisson bracket defined in [LW90].

[44] *Proof:* The sourceless transverse gauge linearized field equation

$$\nabla^\sigma\nabla_\sigma\bar{\gamma}_{\mu\nu} - 2R^\sigma{}_{\mu\nu}{}^\tau\bar{\gamma}_{\sigma\tau} = 0 \tag{85}$$

for the trace reversed metric perturbation $\bar{\gamma}_{\mu\nu} = \delta g_{\mu\nu} - \frac{1}{2}g_{\mu\nu}(g^{\sigma\rho}\delta g_{\sigma\rho})$ determines a unique solution on the entire domain of dependence of Σ given any smooth symmetric tensor fields $\bar{\gamma}_{\mu\nu}$ and $\nabla_n\bar{\gamma}_{\mu\nu}$ on Σ, where n is the unit normal to Σ. (see (13).) If these data satisfy the transverse gauge condition

$$\nabla^\mu\bar{\gamma}_{\mu\nu} \equiv \chi_\nu = 0 \tag{86}$$

constraints then it follows from (82) that for any constraint C

$$\Omega_\Sigma[\{C,\cdot\}_\Delta,\delta]=0. \tag{88}$$

Thus, if we could add some combination of actions of constraints $\{C_i,\cdot\}_\Delta$ to $\{\varphi_I,\cdot\}_\Delta$ so that the sum annihilates the constraints then we would have a solution $\{\varphi_I,\cdot\}_*$ to (53). This can be done, at least formally: A gauge fixing is chosen that completely fixes the gauge transformations generated by the first class constraints, and δ is required to respect this gauge - that is, to annihilate the gauge fixing constraints. Then the *Dirac bracket*,

$$\{\cdot,\cdot\}_*=\{\cdot,\cdot\}_\Delta-\sum_{ij}\{\cdot,C_i\}_\Delta X^{ij}\{C_j,\cdot\}_\Delta, \tag{89}$$

fulfills our requirements. Here the set $\{C_i\}$ includes all constraints, also the gauge fixing constraints, and X is the inverse of the matrix $\{C_i,C_j\}_\Delta$. The Dirac bracket is clearly a pre-Poisson bracket. In fact it also satisfies the Jacobi relations,[45] Note however that several issues arise when this construction is attempted for general relativity, which posses an infinite number of constraints. (A finite set of constraints at each point of Σ). An inverse X to $\{C_i,C_j\}_\Delta$ may not exist even if the latter matrix is non-degenerate - i.e. has no degeneracy vectors; the sum in (89) may not converge; the sums in the proof of the Jacobi relations may not converge.

All the constraints on the ADM variables h and π are first class and generate, via the kinematic bracket $\{\cdot,\cdot\}_\Delta$, diffeomorphisms of the Cauchy surface Σ in the solution spacetime [ADM62]. The effect of such a diffeomorphism of Σ on the the data on Σ is of course equivalent to that of leaving Σ fixed and applying a suitable diffeomorphisms to the spacetime metric field. Since the observables are invariant under such diffeomorphisms the kinematic bracket between an observable and a constraint must vanish. Since X has non-zero matrix elements only between the original first class constraints and the corresponding gauge fixing constraints it follows that the kinematic bracket between two observables, is equal to their Dirac bracket, which in

on Σ and the linearized constraints

$$0=n^\mu\delta G_{\mu\nu}=n^\mu[\nabla_{(\mu}\chi_{\nu)}-1/2g_{\mu\nu}\nabla_\sigma\chi^\sigma-1/2(\nabla^\sigma\nabla_\sigma\bar\gamma_{\mu\nu}-2R^\sigma{}_{\mu\nu}{}^\tau\bar\gamma_{\sigma\tau})] \tag{87}$$

then in the corresponding solutions to (85) also the normal derivative of the transverse gauge condition holds: $\nabla_n\chi_\nu=0$. But taking the divergence of (85) we find that this equation implies $\nabla^\sigma\nabla_\sigma\chi_\nu=0$. The fact that χ and its normal derivative vanish on Σ thus implies that it vanishes on all of the domain of dependence. But then (85) is equivalent to the linearized Einstein vacuum field equation. $\delta g_{\mu\nu}=\gamma_{\mu\nu}=\bar\gamma_{\mu\nu}-1/2g_{\mu\nu}g^{\sigma\tau}\bar\gamma_{\sigma\tau}$ thus solves this equation.

[45] To verify the Jacobi relations for the Dirac bracket note that the kinematic bracket $\{\cdot,\cdot\}_\Delta$ does satisfy the Jacobi relations, and that $\{A,B\}_*=\{A^*,B^*\}_\Delta$ where $A^*=A-\sum_{ij}\{A,C_i\}_\Delta X^{ij}C_j$ and B^* is defined similarly.

turn, by (52), is equal to their Peierls bracket. In other words the Peierls bracket of the observables is equal to the standard ADM bracket between them.

2.3 Gauge transformations

Degeneracy vectors of the presymplectic 2-form are normally associated with gauge transformations. Though it is not strictly necessary for our purpose of obtaining the auxiliary pre-Poisson bracket between initial data it is interesting, and ultimately important for the theory, to see how this works out in the situation we are considering, in which the initial data is specified on a hypersurface with a finite boundary. Here a definition of gauge transformations is proposed and some of its consequences are worked out.

Gauge transformations are transformations of the solutions that affect only those degrees of freedom of the field which are in principle unpredictable. A more precise definition (inspired by that of [LW90]) would be the following:

A map θ from the space of solutions to itself is a gauge transformation iff for any pair C_1, C_2 of disjoint closed sets in spacetime there exists another map θ' from the space of solutions to itself that reduces to θ on the field on C_1 and to the identity on the field on C_2.

Put another way, the gauge transformed solution on any closed portion C_1 of spacetime can always be joined to the untransformed solution on any disjoint closed region C_2, forming another solution. Thus knowledge of the field on all of C_2 does not suffice to determine whether or not the field is transformed by θ on C_1.

Here a slightly different definition will be proposed. As discussed earlier, the developments of smooth initial data are expected to be smooth at $\partial\mathcal{N}$. However disjoint subsets of $\underline{\mathcal{D}}$ which are closed in $\underline{\mathcal{D}}$ may have closures in M which are not disjoint, containing common points on $\partial\mathcal{N}$ which is outside $\underline{\mathcal{D}}$. The requirement that gauge related solutions can be spliced on all pairs of disjoint sets that are closed in $\underline{\mathcal{D}}$ combined with the requirement that the resulting spliced solutions be smooth at $\partial\mathcal{N}$ puts restrictions on the gauge transformations near $\partial\mathcal{N}$. Whether gauge transformations should be restricted in this way or not depends on the usefulness of the notion of gauge obtained. Here I opt to remove these restrictions on the transformations by placing further restrictions on the pairs of subsets C_1, C_2. The resulting set of gauge transformations is certainly simpler as a consequence.

Definition 2.1 *A map θ from the space of solutions $\mathcal{S}$ to itself is a gauge transformation iff for any pair C_1, C_2 of subsets of $\underline{\mathcal{D}}$ having disjoint closures in M there exists another map $\theta' : \mathcal{S} \to \mathcal{S}$ that reduces to θ on the field on C_1 and to the identity on the field on C_2.*

Note that the manifold $\underline{\mathcal{D}}$ here is the union of $int\mathcal{N}$ and the interior of its domain of dependence in some, arbitrarily chosen solution which we take as fiducial. (For instance $\underline{\mathcal{D}}_0$ formed from $\mathcal{N}_0$ and the interior of its domain of dependence in Minkowski space could be used - see subsection 2.1.) As in subsection 2.1 $\mathcal{S}$ consists of the metric fields of the maximal Cauchy developments, mapped via the diffeomorphism of prop. B.23 to $\underline{\mathcal{D}}$.

According to the definition def. 2.1 (and also the previous one) the gauge transformations of general relativity are diffeomorphisms, as one would expect:

Proposition 2.3 *A gauge transformations of general relativity acts on any given solution as a diffeomorphism of $\underline{\mathcal{D}}$ to $\underline{\mathcal{D}}$.*[46]

Proof: Consider a particular solution g to Einsteins field equations on $\underline{\mathcal{D}}$ and a gauge transformation θ. Let C_1 be a compact set in the interior $\mathcal{D}$ of $\underline{\mathcal{D}}$ and C_2 the causal past in $\mathcal{D}$ of a spacelike Cauchy surface Σ_2 of $\mathcal{D}$ to the past of C_1. C_2 is closed in $\mathcal{D}$ since it is the complement of the open set $I^+[\Sigma_2, \mathcal{D}]$ in $\mathcal{D}$. Its closure in M thus intersects $\mathcal{D}$ only on C_2 itself, and thus does not intersect C_1, which, being compact, is already closed in M.

The well known uniqueness theorems for the Cauchy problem of general relativity (see [HE73]) then show that the solution on C_2 determines that on C_1 up to a diffeomorphism, which necessarily maps $\underline{\mathcal{D}} - C_2$ to itself (since $\mathcal{S}$ contains only solutions in which $\underline{\mathcal{D}} - C_2$ is the spacetime of the maximal future Cauchy development of Σ_2). It follows that on C_1, on the given solution, θ is equivalent to a diffeomorphism that maps C_1 to a compact subset of $\mathcal{D}$.

In fact θ is equivalent on all of $\mathcal{D}$ to a diffeomorphism ϕ from $\mathcal{D}$ to itself: If C_1' is a compact subset of $\mathcal{D}$ which contains C_1 then the diffeomorphism on C_1 corresponding to θ may be chosen to be the restriction to C_1 of the diffeomorphism corresponding to θ on C_1'. If the metric on C_1 has no isometries this follows from the fact that the mapping θ of the metric determines a unique diffeomorphism. When there are isometries we are still free to *impose* this condition. Now, because $\mathcal{D}$ is paracompact it may be covered by a sequence of such nested compact sets. If there are no isometries of all of $\mathcal{D}$ then some compact set in the sequence, and all following it, will also be free of isometries so θ defines a unique diffeomorphism on each set in the sequence, such that the diffeomorphisms on the larger sets are extensions of the diffeomorphisms on the smaller sets. θ is therefore equivalent to a diffeomorphism $\phi : \mathcal{D} \to \mathcal{D}$. If $\mathcal{D}$ does have isometries a compact set in the sequence may be chosen that has only the isometries of $\mathcal{D}$ as a whole. The diffeomorphisms equivalent to θ on the smaller sets

[46] A gauge transformation may act as one diffeomorphism on one solution and a different diffeomorphism on another. Thus as a map from $\mathcal{S}$ to $\mathcal{S}$ it is not necessarily equivalent to any one diffeomorphism.

in the sequence as well as on the larger sets may then be chosen to be consistent with the diffeomorphism on this set, and again θ is equivalent to a diffeomorphism $\phi : \mathcal{D} \to \mathcal{D}$, although in this case it is not unique.

This result extends to the bounding hypersurface $int\mathcal{N}$. That is, on all of $\underline{\mathcal{D}}$, including $int\mathcal{N}$, θ is equivalent to a diffeomorphism from $\underline{\mathcal{D}}$ to $\underline{\mathcal{D}}$. To show this we shall demonstrate, using the fact that both g and θg are smooth on $\underline{\mathcal{D}}$, and thus can be smoothly extended to a boundaryless manifold $Z \subset M$ containing $\underline{\mathcal{D}} \supset int\mathcal{N}$, that a suitable extension of the diffeomorphism ϕ to $int\mathcal{N}$ can be constructed.

Let p be a point of $int\mathcal{N}$ and let U be a convex normal neighbourhood of p in Z according to a smooth extension $\hat{g}$ of the metric g to Z. Let q be a point of $U \cap \mathcal{D}$ from which p can be reached via a past directed timelike geodesic ℓ, and suppose that a Riemann $\hat{g}$-normal coordinate chart, y, covering U and based at q is set up. The map ϕ takes q to $q' \in \mathcal{D}$ and the restriction of y to $U \cap \mathcal{D}$ to a new chart y' with origin at q' which is normal with respect to the metric θg. An extension of the chart y' to a slightly larger domain defines, together with the chart y, the extension of ϕ that is needed.

First we need to understand a little more about the image under the diffeomorphism ϕ of the domain $U \cap \mathcal{D}$. Let ℓ° be the segment of the geodesic ℓ which lies in $\mathcal{D}$, and let $\ell^{\circ\prime} = \phi(\ell^\circ)$. $\ell^{\circ\prime}$ is timelike according to θg and past directed, if the time orientation on $\underline{\mathcal{D}}$ is always chosen so that $int\mathcal{N}$ lies to the past of $\mathcal{D}$, because with this convention ϕ preserves the time orientation of timelike curves. Since q' lies in $\mathcal{D}$, and thus in the future domain of dependence, according to θg, of $int\mathcal{N}$ in $\underline{\mathcal{D}}$, but $\ell^{\circ\prime}$ does not cross $int\mathcal{N}$ $\ell^{\circ\prime}$ must be an extendible curve - it must have a past endpoint, p', in $\underline{\mathcal{D}}$. p' cannot lie in $\mathcal{D}$ since ℓ° would then have a past endpoint in $\mathcal{D}$. p' thus lies in $\int\mathcal{N}$. (p' will turn out to be the image of p under the extension of ϕ.)

The same argument applies when p is replaced by any other point $\tilde{p}$ in the open subset of $int\mathcal{N} \cap U$ that lies in the chronological past $I^-[q]$ of q. That is, the image under ϕ of the geodesic segment from q to $\tilde{p}$ (not including $\tilde{p}$ itself) has a past endpoint on $int\mathcal{N}$.

Let $\hat{g}'$ be a smooth extension of θg from $\underline{\mathcal{D}}$ to Z, then the past directed, timelike geodesics from q that define the normal coordinates y' near p' can be extended smoothly through their past end points on $int\mathcal{N} \subset Z$. These extended geodesics can then be used to extend the domain of the normal coordinates y'. The geodesics do not form any caustics on $int\mathcal{N}$ near p': In terms of the metric components

$$\hat{g}'_{\alpha\beta} = \hat{g}'(\frac{\partial}{\partial y'^\alpha}, \frac{\partial}{\partial y'^\beta}) \tag{90}$$

in normal coordinates a caustic occurs at a point if and only if $det[\hat{g}'_{\alpha\beta}]$ approaches zero as the point is approached. But the y' components of the metric θg at a point $r \in \mathcal{D}$ are the same as the y components of the metric g at $\phi^{-1}(r) \in \mathcal{D}$. There can

thus be no caustic at p' since the y chart does *not* break down at p, being good on all of U. The inverse function theorem then implies that the y' coordinates constructed from the extended timelike geodesics form a good chart of a neighbourhood of p' in Z. Since the diffeomorphism $y'^{-1} \circ y$ coincides with ϕ on the portion of its domain V lying in $\mathcal{D}$, and furthermore it maps no point outside $\mathcal{D}$ into $\mathcal{D}$ and $y'(p') = y(p)$, the definition $\phi = y'^{-1} \circ y$ on V extends ϕ as a diffeomorphism to a domain including a neighbourhood of p in Z.

Of course $\phi(p) = p'$. Moreover, the limiting values of the y components of $\hat{g}$ as p is approached from $\mathcal{D}$ are the same as the limiting values of the y' components of $\hat{g}'$ as p' is approached from $\mathcal{D}$, which implies that the actual values of the y components of $\hat{g}$ at p and the y' components of $\hat{g}'$ at p' are equal, because the smoothness of the metrics $\hat{g}$ and $\hat{g}'$ imply that the charts y and y', and the corresponding metric components, are smooth. Thus $\theta g = \phi^* g$ in a neighbourhood of p in $int\mathcal{N}$.

ϕ can be extended in this way to all of $int\mathcal{N}$. If ϕ_1 and ϕ_2 are two extensions of ϕ such that a point $t \in int\mathcal{N}$ lies in the intersection of their domains of definition then, because $\phi_1 = \phi_2$ on $\mathcal{D}$ and both are continuous $\phi_1(t) = \phi_2(t)$. ∎

Now consider linearized gauge transformations. The tangent $\gamma \in L_g$ at a solution g to a one parameter family of gauge transforms of g clearly satisfies the following condition: For all pairs $C_1, C_2 \subset \underline{\mathcal{D}}$ having disjoint closures in M there exists $\gamma' \in L_g$, such that $\gamma' = \gamma$ on C_1 and $\gamma' = 0$ on C_2. I shall call any $\gamma \in L_g$ that satisfies this condition a *linearized gauge transformation*. These can be characterized as follows:

Proposition 2.4 *Linearized gauge transformations are generalized degeneracy vectors of the presymplectic 2-form.*

Proof: The hypersurface independence of $\bar{\Omega}$ implies that any linearized gauge transformation γ_0 which vanishes in a neighbourhood of $\partial\mathcal{N}$ is a degeneracy vector of $\bar{\Omega}$: Let $\Sigma_1, \Sigma_2 \subset \mathcal{D}$ be smooth Cauchy surfaces of $\mathcal{D}$, such that[47]

$$\Sigma_2 \subset I^+[\Sigma_1; \mathcal{D}], \tag{91}$$

and let $C_1' = J^-[\Sigma_1; \mathcal{D}]$ and $C_2 = J^+[\Sigma_2; \mathcal{D}]$. These are disjoint closed subsets of $\mathcal{D}$. However their closures, $\overline{C_1'}$, $\overline{C_2}$ in M intersect on $\partial\mathcal{N}$. A point $p \in \overline{C_1'} \cap \overline{C_2}$ lies in $\overline{D[\mathcal{N}; M]} = \overline{D[\overline{\Sigma}_1; M]} = \overline{D[\overline{\Sigma}_2; M]}$, and thus, by prop. 8.3.2. of [Wald84] any inextendible timelike curve through p must cross $\overline{\Sigma}_1$, at p or later, and $\overline{\Sigma}_2$, at p or earlier. But $\overline{\Sigma}_2 \subset \overline{I^+[\Sigma_1; M]}$ so the crossing of $\overline{\Sigma}_2$ must be after or simultaneous with the crossing of $\overline{\Sigma}_1$. The only consistent possibility is that $p \in \overline{\Sigma}_1 \cap \overline{\Sigma}_2$, which by (91) and prop. B.15 implies that $p \in \partial\mathcal{N}$.

[47] Time ordered sequences of Cauchy surfaces exist by Geroch's theorem, prop. 6.6.8. of [HE73], and may be taken to be smooth by the result of [BS03].

Let C_1 be the support of γ_0 in the causal past of Σ_1. The closure $\overline{C}_1$ of this set in M is a subset of $\overline{C}'_1$ which excludes a neighbourhood of $\partial\mathcal{N}$. $\overline{C}_1$ therefore does not intersect $\overline{C}_2$. By the definition of linearized gauge transformations there must thus exist $\gamma'_0 \in L_g$ such that $\gamma'_0 = \gamma_0$ on C_1 and $\gamma'_0 = 0$ on C_2. Therefore

$$\bar{\Omega}[\gamma_0, \cdot] = \bar{\Omega}_\Sigma[\gamma'_0, \cdot] = \bar{\Omega}_{\Sigma'}[\gamma'_0, \cdot] = 0. \tag{92}$$

Now consider an arbitrary linearized gauge transformation γ and a solution δ to the linearized field equations vanishing in a neighbourhood $U \subset M$ of $\partial\mathcal{N}$. By definition there exists another linearized gauge transformation γ' which is equal to γ on $\mathcal{D} - U$ (which contains the support of δ) and which vanishes on a closed subset of U which contains $\partial\mathcal{N}$ in its interior. Thus

$$\bar{\Omega}[\gamma, \delta] = \bar{\Omega}[\gamma', \delta] \tag{93}$$

and, since γ' vanishes in a neighbourhood of $\partial\mathcal{N}$, this vanishes by (92). This is valid for any $\delta \in L^0_g$ so γ is a generalized degeneracy vector of $\bar{\Omega}$. ∎

This last result and prop. 2.1 imply that, at least when the metric on $\underline{\mathcal{D}}$ is generic (in the sense of prop. 2.1), a linearized gauge transformation must be a smooth diffeomorphism generator - that is, a Lie derivative $\pounds_\xi$ along a smooth vector field ξ. This can in fact be demonstrated directly, without the genericity assumption, by an argument analogous to that used above to characterize the gauge transformations of full general relativity, from the fact that data on a Cauchy surface of $\mathcal{D}$ determines the solution to the linearized field equations up to the addition of terms of the form $\pounds_\xi g_{\mu\nu} = 2\nabla_{(\mu}\xi_{\nu)}$ (see Appendix C). Conversely, it is easy to see that any Lie derivative $\pounds_\xi$ along a smooth vector field ξ is a linearized gauge transformation according to our definition.

The linearized gauge transformations are thus precisely the diffeomorphism generators, they are always generalized degeneracy vectors of $\bar{\Omega}$, and, at least for a generic metric on $\underline{\mathcal{D}}$ all degeneracy vectors are diffeomorphism generators and thus linearized gauge transformations.

It would perhaps be natural to impose a further condition on the linearized gauge transformations that all tangents to full gauge transformations satisfy, namely that the integral curves of ξ do not leave $\underline{\mathcal{D}}$. This would restrict the linearized gauge transformations to only a subset of the generalized degeneracy vectors of $\bar{\Omega}$, although it does not require them to be true degeneracy vectors.

The best - most natural and most useful - choice of definition of gauge transformations in the context of a spacetime with boundaries is not clear to the author. In this section some possible definitions have been presented. Note however that nothing in the remainder of the paper depends on the choice of these definitions. Indeed the

general notion of gauge transformations is not used in the paper, precisely because no clearly preferred definition was found. Instead the classes of transformations considered are identified explicitly in each instance (e.g. diffeomorphisms that preserve a neighbourhood of $\partial\mathcal{N}$).

3 Free initial data and adapted coordinates

3.1 The area parameter

The tangents n_A to the generators that sweep out the branch $\mathcal{N}_A$[48] of $\mathcal{N}$ are also normal to $\mathcal{N}_A$ (prop. B.2). As a consequence $\mathcal{N}_A$ is a null hypersurface (its normals are null vectors) and the 3-metric induced on $\mathcal{N}_A$ by the spacetime metric is degenerate, as there is a vector in the tangent space - namely n_A - which is orthogonal to all tangent vectors. Put another way, if one uses a tangent to the generators as the first vector in a basis of the tangent space of $\mathcal{N}_A$ then the 3-metric takes the form

$$\begin{bmatrix} 0 & 0 & 0 \\ 0 & & \\ 0 & & h_{ij} \end{bmatrix}, \tag{94}$$

where h_{ij} is a symmetric 2×2 matrix.

The degeneracy of the 3-metric implies that the distance between neighbouring points p and q on $\mathcal{N}_A$ does not depend on the component of the (infinitesimal) displacement vector $\vec{pq}$ parallel to the generators. Similarly the area,

$$\mathcal{A} = \sqrt{t_1 \cdot t_1 \, t_2 \cdot t_2 - (t_1 \cdot t_2)^2}, \tag{95}$$

of an infinitesimal parallelogram in $\mathcal{N}_A$ spanned by vectors t_1 and t_2 based at $p \in \mathcal{N}_A$ does not depend on the components of t_1 and t_2 along the generators. It depends on p and on the set of generators cut by the parallelogram, but not on the "angle" at which it cuts these, that is, on the tangent plane of the parallelogram. This fact makes possible a very useful (non-affine) parametrization of the generators. It implies that the cross sectional area of an infinitesimal bundle of generators neighbouring a given generator γ, and terminating on a surface of area $\bar{\mathcal{A}}$ in S_A, depends only on the point $p \in \gamma$ at which the cross section is taken, and (linearly) on $\bar{\mathcal{A}}$. In other words, the factor $\mathcal{A}(p)/\bar{\mathcal{A}}$ by which the area expands following the generators from S_A to p depends only on p. The expansion factor can therefore be used to parametrize γ, provided it increases or decreases monotonically along γ.

[48] Here and from here on subscripts $A, B, ...$ represent indices ranging over L and R.

We shall use the square root of the expansion factor,

$$r = \sqrt{\mathcal{A}/\bar{\mathcal{A}}}, \tag{96}$$

to parametrize the generators. The cross sectional area of a bundle of neighbouring generators is then proportional to r^2, which means that r is an *area parameter*. That is, $r(p)$ is proportional to the distance from p to the caustic point, where neighbouring generators focus and $\mathcal{A} = 0$, inferred from the area subtended at the caustic by a standard disk at p by assuming that this area falls as $1/distance^2$ as in flat spacetime. [49]

As mentioned in subsection 2.1 we shall consider only initial data such that the generators of a given branch, $\mathcal{N}_L$ or $\mathcal{N}_R$, of $\mathcal{N}$ are either everywhere diverging ($\mathcal{A}$ increasing) or everywhere converging toward the future ($\mathcal{A}$ decreasing). This ensures that r is a good parameter on each generator of the branch.

Parametrizing the generators, and the initial data on them, by r makes it easy to incorporate the condition that $\mathcal{N}_L$ and $\mathcal{N}_R$ are truncated before their generators reach a caustic. One simply requires that each branch corresponds to an interval of positive, non-zero, values of r. [50] The use of the area parameter also simplifies the mathematics of the null initial value problem. This was noted and exploited by Gambini and Restuccia [GR78] to obtain an expansion in powers of Newton's constant for the brackets between the main null initial data.

[49] In vacuum general relativity a bundle of neighbouring null geodesics is either incomplete or has at least one caustic, except in the special case that its cross sectional area is strictly constant along the bundle. (This follows from the Raychaudhuri equation discussed in the next paragraph.) Such constant cross section bundles do not exist in generic vacuum solutions (see prop. 4.4.5. of [HE73] and the discussion which follows it). If a bundle of null geodesics has several caustics, it is most natural to r to be a measure of distance to the nearest caustic in the direction along the bundle in which r is decreasing. Of course this is just an issue of interpretation. (96) defines r regardless of the interpretation adopted.

[50] This does not in itself guarantee that the generators do not cross in spacetime, just that *neighbouring* generators do not (more precisely, that the separation of neighbouring generators does not become zero *to first order* in their separation on S_0). But recall that we are considering Cauchy developments, and in a Cauchy development of initial data on $\mathcal{N}$, the generators of $\mathcal{N}$ never intersect (except of course at their starting points on S_0). [If $\mathcal{N}$ intersects itself in a solution to Einstein's field equations then (a portion of) the domain of dependence of $\mathcal{N}$ in this solution is represented in the catalogue of Cauchy developments of $\mathcal{N}$ by a covering manifold (see appendix B prop. B.6).]

If the reader prefers not to represent spacetime by a covering manifold an alternative argument is that in order to calculate the brackets of the data along a given generator γ one may use instead of $\mathcal{N}$ an initial data surface $\mathcal{N}'$ swept out by the generators emerging from a sufficiently small disk $S_0' \subset S_0$ containing the base point of γ in S_0 such that these generators do *not* cross.

3.2 A geometrical description of the initial data

We now turn to the initial data, beginning with a coordinate free description. All the data have an interpretation in terms of the geometry of the corresponding solution, but first let us consider $\mathcal{N}$ and the initial data on their own, prior to embedding in the solution spacetime.

The set of initial data that we will consider consists of a 3-metric on $\mathcal{N}$ and further data specified on S_0 only. The 3-metric is specified by two degenerate, positive semi-definite 3-metrics g_L and g_R defined on $\mathcal{N}_L$ and $\mathcal{N}_R$ respectively. g_L and g_R are required to be smooth and to match at S_0 in the sense that they induce the same 2-metric on S_0. The degeneracy subspace N_p^A of g_A at every point $p \in \mathcal{N}_A$ is one dimensional, and the integral curves of these subspaces, which will be called the "generators" of $\mathcal{N}_A$, form a congruence that threads the cylinder $\mathcal{N}_A$ along its axis. That is, each integral curve originates on S_0 and terminates on S_A. The congruence as a whole defines a (trivial) fibration of $\mathcal{N}_A$ with the generators being the fibres and S_0 the base space.

The data on S_0 are most easily described in terms of two fields, χ and ω, that depend on a choice of parametrization of the generators. We shall therefore suppose that a good parametrization has been (arbitrarily) chosen on the generators. The parametrization defines fields of tangent vectors on $\mathcal{N}_L$ and $\mathcal{N}_R$ which will be denoted, like the tangent vectors to the parametrized generators in the spacetime context, by n_L and n_R respectively.

χ is a smooth scalar field on S_0. ω is a smooth 1-form field on S_0, co-tangent to S_0. Under a change of parametrization such that n_L and n_R are rescaled by factors α_L and α_R

$$\chi \rightarrow \alpha_L \alpha_R \chi \tag{97}$$

$$\omega \rightarrow \omega + \underset{\Leftarrow}{d} \log \alpha_L - \underset{\Leftarrow}{d} \log \alpha_R, \tag{98}$$

where a $\Leftarrow$ beneath a form indicates that the pullback of the form to S_0 is to be taken.

In the corresponding solution to Einstein's vacuum equations the 3-metric on $\mathcal{N}$ matches the 3-metric induced on the embedding of $\mathcal{N}$ by the spacetime geometry (this means of course that the "generators" defined as the integral curves of the degeneracy subspaces of the 3-metric coincide with the generators of the embedding of $\mathcal{N}$) and χ and ω are related to the spacetime metric and connection via

$$\chi = n_L \cdot n_R \tag{99}$$

and

$$\omega = \frac{n_L^\mu \underset{\Leftarrow}{\nabla} n_{R\,\mu} - n_R^\mu \underset{\Leftarrow}{\nabla} n_{L\,\mu}}{n_L \cdot n_R}. \tag{100}$$

χ thus measures the component of the spacetime metric not captured by the 3-metrics g_L and g_R of $\mathcal{N}$ at S_0, while ω is somewhat akin to an extrinsic curvature, since it measures an aspect of the derivatives along S_0 of its two null normals, n_L and n_R.

Note that the sign of χ is determined once the sense of n_L and of n_R are chosen. If both point away from S_0, or both toward S_0, then χ must be negative, for then n_L and n_R are both null future directed or both null past directed when $\mathcal{N}$ is embedded in a solution spacetime, so their inner product must be negative.

The initial data χ and ω have been postulated to transform under a change of parametrization of the generators in the same way as the solution spacetime quantities that they correspond to, so the correspondence does not depend on the parametrization chosen.

An interesting alternative expression for ω in terms of the spacetime geometry can be obtained if one extends both n_L and n_R to all of $\mathcal{N}$ in such a way that both are orthogonal to the cross sections of $\mathcal{N}$ cutting the generators at a constant parameter value. Then

$$\omega = \frac{[n_L, n_R]}{n_L \cdot n_R}, \tag{101}$$

where the Lie bracket, a vector, is mapped to a 1-form using the spacetime metric. (The right side is called the *normalized twist* [Epp95] but is not to be confused with the "twist" of a single congruence [Wald84] which always vanishes for the generators of a null hypersurface.)

To see this suppose a tangent vector s of S_0 is Lie dragged along n_A to all of the branch $\mathcal{N}_A$. This defines a vector field s orthogonal to both n_L and n_R, since s is everywhere tangent to the isoparametric cross sections. The Lie derivative of the orthogonality relation $s^\mu n_{B\,\mu} = 0$ together with the fact that s satisfies $\pounds_{n_A} s = 0$ implies

$$0 = s^\mu \pounds_{n_A} n_{B\,\mu} = s^\mu \nabla_{n_A} n_{B\,\mu} + n_{B\,\mu} \nabla_s n_A^\mu. \tag{102}$$

Thus for all s tangent to S_0, $\omega \cdot s$ takes the same value whether computed using the expression (100) or the projection of the normalized twist (101), proving their equivalence.

From (101) it is clear that ω measures the non-integrability at S_0 of the normal planes to the isoparametric sections of $\mathcal{N}$. Integrability cannot in general be achieved by reparametrizing the generators because the transformation law (98) implies that the curl of ω on S_0 is independent of the parametrization.

Sachs [Sac62] and Rendall [Ren90] have given arguments that imply that any choice of these data (satisfying certain inequalities)[51] on $\mathcal{N}$ define a solution to Ein-

[51] The vacuum Einstein equations imply, via the Raychaudhuri focusing equation ([Wald84] eq. 9.2.32), that if the cross sectional area of an infinitesimal bundle of neighbouring generators is

stein's field equations that is unique up to diffeomorphisms. More precisely, Sachs considered these data expressed in a special coordinate system adapted to the data - in which the generators lie along coordinate axes and each generator is parametrized by a coordinate which becomes an affine parameter in the corresponding solution spacetime - and argued that the solution metric exists and is unique in a particular coordinate system adapted to the solution which extends his coordinates on $\mathcal{N}$ to spacetime. Rendall then proved that Sachs' claim is true, at least in a neighbourhood of S_0 in the causal domain of dependence $D[\mathcal{N}]$ of $\mathcal{N}$.

The chief advantage of using coordinates adapted to the data, such as Sachs' coordinates, is that it makes it easier to identify freely specifiable data. The data g_L, g_R, χ and ω are not themselves freely specifiable since g_L and g_R are constrained to be degenerate, with restrictions on the degeneracy subspaces. Taking the generators as coordinate axes reduces this constraint to the requirement that certain metric components vanish (see (94)). The use of a coordinate adapted to the data to parametrize the generators further reduces the freely specifiable data. Sachs normalizes the parameters on the generators so that $\chi = -1$ always. Moreover, the requirement that the parameters become affine parameters in the matching solution implies a constraint on the parameter dependence of the 3-metric on $\mathcal{N}$. The cross sectional area of an infinitesimal bundle of neighbouring generators must satisfy the Raychaudhuri focusing equation corresponding to an affine parametrization ([Wald84] eq. 9.2.32) with the Ricci curvature term set to zero, which substantially reduces the independently specifiable metric data.

Another way to view the constraint on the metric components just mentioned is the following: Given *any* 3-metric on $\mathcal{N}$ satisfying the conditions of smoothness and degeneracy we have required of the initial data, and satisfying the inequalities explained in footnote 51, there is a parametrization of each generator, unique up to an affine transformation, such that the metric satisfies the constraint. If this parameter, which I will term a "proto affine parameter" is adopted the metric must satisfy the constraint, but only because of the choice of parameter, and not because of Einstein's field equations. The field equations imply that in the matching solution the proto affine parameter becomes an affine parameter of the spacetime geometry. This argument will be developed in detail in subsection 3.5.

We will define both an almost freely specifiable data set and a completely free data set using charts similar to those of Sachs but with the proto affine parameter replaced by the area parameter r defined in (3.1). The area parameter provides a

decreasing in one direction along the bundle at one point then it must continue to decrease in the same direction until it reaches zero. That is to say,if the derivative of the area by any differentiable parameter of the generators is negative at a point then it must remain negative until the area vanishes. This imposes inequalities on the 3-metric on $\mathcal{N}$, although it does not imply any restriction on the variables Sachs used to describe the initial data.

good parametrization of the generators of a branch of $\mathcal{N}$ iff the cross sectional area of infinitesimal bundles of neighbouring generators in the branch is either everywhere increasing or everywhere decreasing toward the future. This is not the case in all solutions so our formalism cannot be applied to all initial data compatible with the field equations, but only to data satisfying this restriction on the 3-metric on $\mathcal{N}$.[52] However, as explained in subsection 2.1, this leads to relatively little loss of generality in our results. The causality requirement implies that only data living on the same generator have non-zero brackets. In the calculation of the brackets on the generators through a point $p \in S_0$ we may therefore replace $\mathcal{N}$ by $\mathcal{N}' \subset \mathcal{N}$ swept out by the generators through a compact subset S_0' of S_0 containing p in its interior. If the expansion rate of the congruence of generators of $\mathcal{N}_L$ and that of the generators of $\mathcal{N}_R$ are both non-zero at p (the generic case) then S_0' may be chosen so that these expansion rates are non-zero and of uniform sign on S_0'. If the expansion rate at S_0' of the generators of a branch is negative then by the field equations and the Raychaudhuri equation it will be negative on the whole branch, and r will decrease monotonically on the generators. If the expansion rate is positive at S_0' then r increases monotonically along each generator until it leaves the branch or until r reaches a maximum. In the latter case our results apply until the maximum is reached. Only if the expansion rate of the generators at p of one of the branches of $\mathcal{N}$ is zero are our methods inapplicable.

In the following subsection the coordinates that will be used to define our almost free and completely free initial data will be defined precisely. The relation between these data and Sachs' data is treated in detail in subsection 3.5.

3.3 Coordinate systems and free initial data

Three special coordinate charts will be used to represent the different elements of the initial data. The a_R chart, with coordinates $a_R^\alpha = (u_R, r_R, y_R^1, y_R^2)$, covers $\mathcal{N}_R$ and a spacetime neighbourhood of $int\mathcal{N}_R$, is adapted to the generators of $\mathcal{N}_R$, and is fixed in the manifold (i.e. solution independent) on $S_R \subset \partial\mathcal{N}$. The a_L chart, which will be defined in strict analogy with the a_R chart, covers $\mathcal{N}_L$ and a spacetime neighbourhood of $int\mathcal{N}_L$, is adapted to the generators of $\mathcal{N}_L$, and is fixed to the manifold on $S_L \subset \partial\mathcal{N}$. Finally, the b chart, with coordinates $b^\mu = (v^+, v^-, \theta^1, \theta^2)$, covers all of $\mathcal{N}$ and a spacetime neighbourhood of $int\mathcal{N}$ and is adapted to the generators of both branches of $\mathcal{N}$, but is not *a priori* fixed anywhere.

Greek lowercase indices $\alpha, \beta, ...$ from the beginning of the alphabet will always refer to an a coordinate basis (of the branch $\mathcal{N}_A$ under consideration). Greek uppercase indices $\Lambda, \Xi ...$ refer to the b coordinate basis. Lowercase Latin indices $i, j, ...$ from

[52] This restriction is not a *constraint* because it implies only that the 3-metric satisfies inequalities, and not equations.

the latter part of the alphabet range over $\{1,2\}$ and will be used to identify the two adapted coordinates y^1_A and y^2_A and their corresponding coordinate basis vectors, while lower case Latin indices $a, b, ...$ from the beginning of the alphabet, which also range over $\{1,2\}$, identify the coordinates θ^1 and θ^2 and their basis vectors.

The chart $a^\alpha_A = (u_A, r_A, y^1_A, y^2_A)$ adapted to $\mathcal{N}_A$ is defined in three steps. First smooth, fixed (not solution dependent), coordinates y^1_A and y^2_A are chosen on S_A. Next this coordinate system is extended to a chart on all of $\mathcal{N}_A$ by convecting the y^i_A along the generators, i.e. setting them to be constant along the generators, and introducing the coordinate r_A, taken to be the area parameter along the generators defined in subsection 3.1. Thus on $\mathcal{N}_A$ the two y coordinates identify the generators and r_A identifies the points on each generator. Finally coordinates are defined on a spacetime domain containing $int\mathcal{N}_A$ in its interior: Each constant r_A section of $\mathcal{N}$ is a two dimensional spacelike disk and thus posses two null normals at each point, and two corresponding normal null geodesics, One is the generator of $\mathcal{N}_A$ through the point and the other is transverse to $\mathcal{N}_A$. To extend the coordinate system to a neighbourhood of $\mathcal{N}_A$ the three coordinates y^1_A, y^2_A, and r_A are convected along the transverse normal null geodesics and a fourth coordinate, u_A, which parametrizes these geodesics is defined by the requirements $u_A = 0$ on $\mathcal{N}_A$ and $\partial_{u_A} \cdot \partial_{r_A} = -1$.

To lighten the notation the subscript ("A") identifying the branch $\mathcal{N}_A$ to which the coordinates a_A are adapted will be dropped from here on when there is little risk of confusion.

The components of the metric on a branch $\mathcal{N}_A$ take a very restricted form in the a coordinates adapted to that branch. The coordinate basis vectors ∂_r and ∂_u are null, and have inner product $\partial_r \cdot \partial_u = -1$. Moreover both are orthogonal to the constant (u, r) surfaces. Thus the line element takes the very simple form

$$ds^2 = -2dudr + h_{ij}dy^i dy^j \tag{103}$$

on $\mathcal{N}_A$, where h_{ij} is a symmetric 2×2 matrix which must be positive definite in order that the spacetime metric be Lorentzian with signature $-+++$. The induced 3-metric on $\mathcal{N}_A$ is seen to be degenerate and takes precisely the form (94) obtained in subsection 3.1. The line element on *any* 2-surface cutting a cross section of the congruence of generators is $ds^2 = h_{ij}dy^i dy^j$. This means in particular that area density of the cross section is,

$$\rho = \sqrt{det[h_{ij}]}, \tag{104}$$

the root of the determinant of the induced 2-metric. (As expected this depends only on position in $\mathcal{N}_A$, and not on the tangent plane of the cross section.) The value of the coordinate r, the area parameter, at a point $p \in \mathcal{N}_A$ is thus

$$r(p) = \sqrt{\rho(p)/\bar{\rho}(\gamma)} \tag{105}$$

where $\bar{\rho}(\gamma)$ is the value of ρ at the endpoint on S_A of the generator γ through p. Equivalently

$$\rho(r, y^i) = r^2 \bar{\rho}(y^i). \tag{106}$$

The only freedom in ρ is thus its boundary value $\bar{\rho}$ on S_A.

The remaining freedom in h_{ij} resides in the conformal[53] 2-metric, a unimodular (determinant equals 1) 2×2 matrix defined by

$$e_{ij} = h_{ij}/\rho. \tag{107}$$

Information about the metric geometry of $\mathcal{N}_A$ is also found in the range of values the a coordinates take on $\mathcal{N}_A$. (y^1, y^2) ranges over a fixed (solution independent) domain diffeomorphic to a disk in $\mathbb{R}^2$. r on the, other hand, ranges on each generator from 1 on S_A to a value $r_0(y)$ on S_0 (depending on the generator). The function $r_0(y)$ depends on the solution metric, since a variation of the metric will in general change the rate at which the generators are focused, contracting or expanding cross sections of bundles of neighbouring generators, and thus affects r_0. [r_0 may be either greater than 1, (generators converging toward the future) or less than 1 (generators diverging), and though r_0 typically varies over S_0, it never passes through 1 because of the restrictions that have been imposed on the initial data to ensure that the area parameter is good on every generator.]

Further information is contained in the map ϕ from the coordinates y_R to the coordinates y_L on S_0. A perturbation of the solution metric, for instance a gravitational wave pulse passing through $\mathcal{N}_R$ but not $\mathcal{N}_L$, will in general affect which generator from S_R intersects a given generator from S_L, and thus which values y_R and of y_L correspond to the same point on S_0. The map ϕ is thus solution dependent.

ϕ and the functions $r_0(y)$, $\bar{\rho}(y)$, and $e_{ij}(r, y)$ on each branch determine the 3-metric on $\mathcal{N}$ modulo the action of a group $\mathcal{D}^\circ_\mathcal{N}$ of homeomorphisms $\mathcal{N} \to \mathcal{N}$ which map each branch diffeomorphically to itself and reduce to the identity on S_R and S_L:[54] The functions $r_{L0}(y_R)$, $r_{L0}(y_L)$ and ϕ alone, without further specification of the 3-metric on $\mathcal{N}$, determine the a_R and a_L coordinates on $\mathcal{N}$ up to the action of $\mathcal{D}^\circ_\mathcal{N}$. To see this consider the transformation of the a charts due to a change of the metric, within the class of metrics we allow on $\mathcal{N}$, which preserves $r_{L0}(y_R)$, $r_{L0}(y_L)$ and ϕ. (Recall that once the y coordinates are fixed on S_L and S_R the a charts are completely determined by the metric, so this type of transformation is the only freedom that remains in these charts once $r_{L0}(y_R)$, $r_{L0}(y_L)$ and ϕ are given.) The

[53] It is invariant under rescaling of the metric, hence the name.

[54] These homeomorphisms could perhaps be called diffeomorphisms since they respect all the natural differentiable structure of $\mathcal{N}$. Furthermore, by the Whitney extension theorem the homeomorphisms in $\mathcal{D}^\circ_\mathcal{N}$ can always be extended to diffeomorphisms in a spacetime neighbourhood of $\mathcal{N}$ taking each branch of $\mathcal{N}$ to itself and leaving S_L and S_R invariant.

displacement of the a coordinate points induced on each branch by this change of metric leave S_L and S_R invariant, since the coordinates are fixed there. Furthermore, the invariance of $r_0(y)$ on each branch (and the smoothness of the metric) implies that these displacements define a diffeomorphism of the branch to itself, with S_0 mapped to S_0. Finally, the invariance of ϕ implies that the diffeomorphisms on the two branches induce the *same* diffeomorphism on S_0, assuring that the transformation of the a_L and a_R charts is an element of $\mathcal{D}^\circ_{\mathcal{N}}$.

If in addition to $r_{L0}(y_R)$, $r_{L0}(y_L)$ and ϕ the non-zero a components of the 3-metric (i.e. $h_{ij} = r^2\bar{\rho}(y)e_{ij}(r,y)$) are given on each branch, then the 3-metric is determined up to homeomorphisms in $\mathcal{D}^\circ_{\mathcal{N}}$. This is the most one could expect, since all these quantities are invariant under the action of $\mathcal{D}^\circ_{\mathcal{N}}$ on the 3-metric.

In the calculation of the brackets we shall use essentially these functions to represent the 3-metric part of the initial data. In particular the conformal 2-metric on $\mathcal{N}$, specified by the functions $e_{Rij}(r_R, y_R)$ and $e_{L\,ij}(r_L, y_L)$, will represent the bulk of the initial data. The remaining data will ultimately be represented by fields living on S_0 - fields equivalent to ϕ, $r_{A\,0}$, and $\bar{\rho}_A$, and χ and ω corresponding to a particular parametrization of the generators.

These quantities are not entirely unconstrained. We require that the induced 3-metric be consistently defined at S_0 in the sense that the same 2-metric is induced on S_0 from the 3-metrics of either branch. Taking into account the transformation from y_L to y_R coordinates this leads to the conditions

$$\bar{\rho}_R r^2_{R\,0} = |det\frac{\partial y_L}{\partial y_R}|\bar{\rho}_L r^2_{L\,0} \tag{108}$$

and

$$e_{R\,ij} = \frac{\partial y^m_L}{\partial y^i_R}\frac{\partial y^n_L}{\partial y^j_R}|det\frac{\partial y_R}{\partial y_L}|e_{L\,mn}, \tag{109}$$

and of course e_{ij} is required to be symmetric and unimodular.

The scheme of two overlapping adapted charts with solution dependent transformations between them is rather complicated. Why not base our adapted coordinates at S_0, instead of S_R or S_L? The coordinates $b^\mu = (v^+, v^-, \theta^1, \theta^2)$ define such a chart: θ^1 and θ^2 are coordinates on S_0 which are convected along the generators to all of $\mathcal{N}$. v^- and v^+ are area parameters on the generators of $\mathcal{N}_R$ and $\mathcal{N}_L$ respectively that are normalized to 1 on S_0. v^+, θ^1, and θ^2 are extended to a spacetime region by convecting them from $\mathcal{N}_L$ along the congruence of null geodesics that are normal to the constant v^+ sections of $\mathcal{N}_L$ and transverse to $\mathcal{N}_L$, and v^- is similarly extended by convecting it in the same way from $\mathcal{N}_R$.

The b coordinates will be used to represent data living on S_0, and to facilitate comparison with Sachs' initial data. It is tempting to express all the data in terms of these coordinates. In fact the brackets will ultimately be stated for data referred to

this chart. However we will not use such data to *calculate* the brackets. To solve (53) for the auxiliary pre-Poisson bracket we need to be able to identify those variations of the metric that vanish (in a fixed chart) in a neighbourhood of $\partial\mathcal{N}$ from their actions on the initial data. But even variations that vanish near $\partial\mathcal{N}$ do in general deflect the generator of $\mathcal{N}_A$ emerging from a given point of S_0, changing its course all the way to S_A, and thus would produce a variation in the b coordinates at S_A.[55] Therefore data that are local functions of the metric components and their derivatives in the b chart generally vary at $\partial\mathcal{N}$ under such variations, complicating their identification. It would be simpler if the variations that vanish near $\partial\mathcal{N}$ also left the initial data associated with points near $\partial\mathcal{N}$ invariant.

This is the case for data constructed from the a coordinate components of the metric. The variations that leave the metric invariant near $\partial\mathcal{N}$ also leave the a coordinate components of the metric invariant near $\partial\mathcal{N}$, because such a variation leaves the a coordinates themselves invariant in a neighbourhood of $\partial\mathcal{N}$: The coordinates y_A are *fixed* on S_A, so a variation δ that vanishes in a spacetime neighbourhood W of $\partial\mathcal{N}$ clearly leaves the generator corresponding to given y^i_A invariant in a neighbourhood of S_A. Furthermore any generator originating within a sufficiently small neighbourhood U of ∂S_0 in S_0 remains inside W until it leaves $\mathcal{N}$ (See prop. B.8). Such generators are entirely undisturbed by δ. It follows that there exists a neighbourhood V of $\partial\mathcal{N}$ in $\mathcal{N}$, possibly smaller than $W \cap \mathcal{N}$, such that $\delta a_A = 0$ on $V \cap \mathcal{N}_A$. The construction of the a_A coordinates off $\mathcal{N}_A$ then implies that these are in fact invariant in a spacetime neighbourhood of $\partial\mathcal{N}_A \cap \mathcal{N}_A$.

The chief condition defining the bracket on initial data is that the equation (53),

$$\delta\varphi = \bar{\Omega}[\{\varphi, \cdot\}_*, \delta], \tag{110}$$

holds for all initial data φ and all variations $\delta \in L^0_g$ - which is to say all δ satisfying the linearized field equations and vanishing in a spacetime neighbourhood of $\partial\mathcal{N}$. Under such variations

$$\delta e_{A\,ij} = 0 \quad \text{in a neighbourhood of } \partial\mathcal{N} \tag{111}$$

and

$$\delta\bar{\rho}_A = 0. \tag{112}$$

[55] The b coordinates can be held fixed near the end S_A of one branch $\mathcal{N}_A$ under variations of the metric vanishing near the boundary by giving the θ coordinates fixed values on S_A and then convecting them to S_0 along the generators, and from there to the other branch. The θ would then be given by a solution independent function of the y_A coordinates, or at least by one that is invariant under the variations being considered. However, since it is easily shown that the map from the y_L to the y_R coordinates varies under variations of the solution, even variations that vanish near $\partial\mathcal{N}$, these θ cannot be invariant at the end of the other branch. Thus there is no choice of θ which makes the b coordinates invariant near all of $\partial\mathcal{N}$ under variations of the metric that vanish there.

I shall solve (110) for the auxiliary bracket imposing only the restrictions (111) and (112) on the variations δ. This is *a priori* a weaker restriction than $\delta \in L^0_g$, which requires that δ vanishes in a whole spacetime neighbourhood of $\partial\mathcal{N}$. But certainly if (110) holds for our larger class of δs then *a fortiori* it holds for $\delta \in L^0_g$.

On $\mathcal{N}$ the a and b coordinates are related in a fairly simple manner. On $\mathcal{N}_R$ the coordinates $b^\mu = (v^+, v^-, \theta^1, \theta^2)$ can be expressed in terms of the a_R chart as

$$v^+ = 1 \quad v^- = r_R/r_{R0}(y_R) \quad \theta^a = f^a_R(y_R), \tag{113}$$

where f_R is a diffeomorphism from $\mathbb{R}^2$ to $\mathbb{R}^2$. Similarly on $\mathcal{N}_L$ the b^Λ are related to the a^α_L via

$$v^+ = r_L/r_{L0}(y_L) \quad v^- = 1 \quad \theta^a = f_L(y_L). \tag{114}$$

Of course $f_R = f_L \circ \phi$ where ϕ is the (solution dependent) diffeomorphism from y_R to y_L coordinates on S_0.

One could take f_L to be the identity map (i.e. $\theta = y_L$) and $f_R = \phi$. However it will be more convenient not to assume any particular relationship between the θ and y charts. It will be assumed that the θ coordinates of a point in S_0 depends only on the y_L and y_R coordinates of that point and possibly on the initial data on the generators through the point. That way the b coordinates, like the a coordinates, move along with the initial data when these are acted on by a homeomorphism in $\mathcal{D}^\circ_\mathcal{N}$, and the components of the data in the b chart are invariant under such homeomorphisms.

The parameters v^+ and v^- on the generators of $\mathcal{N}_L$ and $\mathcal{N}_R$ respectively define tangent vectors to these generators:

$$n_- = \partial_{v^-} \qquad \text{on } \mathcal{N}_R \tag{115}$$

$$n_+ = \partial_{v^+} \qquad \text{on } \mathcal{N}_L \tag{116}$$

and define corresponding initial data χ_v and ω_v which, in a solution matching the initial data, are given by

$$\chi_v = n_+ \cdot n_- \tag{117}$$

$$\omega_{v\,a} = \frac{n_+ \cdot \nabla_a n_- - n_- \cdot \nabla_a n_+}{n_+ \cdot n_-}. \tag{118}$$

Another datum, which will be used in place of $\bar\rho_L$ and $\bar\rho_R$, is the area density on S_0 in θ coordinates:

$$\rho_0 = r^2_{R\,0}\bar\rho_{y\,R}|\det[\frac{\partial y_R}{\partial\theta}]| = r^2_{L\,0}\bar\rho_{y\,L}|\det[\frac{\partial y_L}{\partial\theta}]|. \tag{119}$$

The two data $\bar\rho_L$ and $\bar\rho_R$ can be replaced by a single datum because of the constraint (108) between them, which is expressed by the second equality of (119).

The preceding considerations show that a possible initial data set for general relativity consists of

- $e_{L\,ij}(r_L, y_L)$ on $\mathcal{N}_L$ and $e_{R\,ij}(r_R, y_R)$ on $\mathcal{N}_R$,

and on S_0

- $r_{L\,0}(y_L)$ and $r_{R\,0}(y_R)$,
- the maps $f_L : y_L \to \theta$ and $f_R : y_R \to \theta$,
- $\rho_0(\theta)$,
- $\chi_v(\theta)$,
- $\omega_{v\,a}(\theta)$.

These will called the *boundary fixed coordinate data* (BFC data) since they are referred to charts that are fixed in the manifold on portions of the boundary $\partial\mathcal{N}$ of the initial data hypersurface under the variations of the solution being considered.[56] They are subject to the one constraint (109) requiring the consistency of the definition of the conformal 2-metric at S_0 (and of course e is also required to be symmetric and unimodular).

When using the BFC data we shall drop the subscript v on χ and ω. χ and ω corresponding to other parametrizations of the generators will have no role to play. It will also turn out to be convenient to use instead of f_L and f_R their inverses, s_L and s_R. Finally, χ, will often be represented by $\lambda = -\log|\chi|$. The sign of χ is uniform on S_0 for the solutions and the $\mathcal{N}$ we admit, and does not change under variations, so taking the absolute value represents no real loss of information.

The domains of sensitivity[57] of all these data are such that the causality condition on the auxiliary pre-Poisson bracket implies that data living on different generators have vanishing bracket. These domains are confined either to only one generator or to the pair of generators emerging from a single point of S_0: The domain of sensitivity of e at a point p on a generator γ is the segment of γ from p to $\partial\mathcal{N}$, that of $r_{A\,0}$ at a point $p_0 \in S_0$ is the whole generator of $\mathcal{N}_A$ originating at p_0, that of $\theta^a(y_R) = f_R^a(y_R)$ is by assumption confined to the pair of generators originating in the point of S_0 specified by θ. The domains of sensitivity of all the remaining data at the same values of θ^a are also contained in the union of these generators.

We shall calculate the brackets between the BFC data, but ultimately the brackets will be expressed in terms of a completely free data set consisting of

[56] Since the variations of the metric under consideration do not affect generators originating sufficiently close to ∂S_0 even the b chart is fixed in a sufficiently small neighbourhood of ∂S_0 in S_0, which is where the data referred to the b chart live.

[57] Recall that we have defined the domain of sensitivity a functional F of the spacetime metric to be the support of the functional gradient $\delta F/\delta g_{\mu\nu}$ of F. Thus perturbations of the metric in this domain, and only in this domain, affect the value of F to first order.

- $e_{ab}(v,\theta)$, the conformal 2-metric on constant v^+, v^- surfaces in b coordinates, specified on all of $\mathcal{N}$

and

- $r_{L\,0}$, $r_{R\,0}$, s_L, s_R, ρ_0, λ, ω_a specified on S_0.

The data $r_{A\,0}$ and f_A (or s_A) define the transformation from the a_A chart to the b chart on $\mathcal{N}_A$, thus once these data are given specifying e_{ab} is equivalent to specifying $e_{A\,ij}$. Recall that because of the degeneracy of the 3-metric of $\mathcal{N}$ the induced metric at a point p on a two dimensional spacelike cross section of $\mathcal{N}$ depends only on $p \in \mathcal{N}$, and not on the tangent plane of the cross section. Thus

$$e_{ab} = \partial_a y^i_A \partial_b y^j_A | \det \frac{\partial \theta}{\partial y_A} | e_{A\,ij} \tag{120}$$

in complete analogy with (109).

The only constraint on the BFC data, (109), simply requires that e_{ab} obtained from e_L, $r_{L\,0}$ and s_L agrees with e_{ab} obtained from e_R, $r_{R\,0}$ and s_R at S_0. It does not limit e_{ab} itself. For this reason we shall refer to this new data set as the completely free (CF) data.

The data $r_{A\,0}$, will turn out to play a somewhat secondary role. Their variations can be eliminated from the presymplectic 2-form. This seems natural as they essentially specify where the generators of the branches of $\mathcal{N}$ have been cut off, something that we are free to change without changing the solution.

3.4 Variations of fields in the a and b charts

The notion of variations of fields, i.e. the derivative of the fields along a one parameter family of field configurations, is fundamental to the variational principle, and the symplectic potential and presymplectic 2-form constructed from it. We have defined the variation of a field on a manifold in terms of a chart fixed to the manifold: The components of the variation in the fixed chart are the variations of the corresponding components of the field in this chart. The transformation of the components of the variation from one fixed chart to another is straightforward since the map from the old to the new chart is field independent. Thus the variations of tensor components transform as do the original tensor components, defining a tensor field, and the variation of a connection also forms a tensor field.

The expression (39) for the presymplectic 2-form therefore has a straightforward interpretation if it is supposed that the field components are referred to a chart fixed in the manifold. However we wish to express the presymplectic 2-form in terms of the BFC data, which consists of metric and connection components in field dependent

coordinate systems. How are variations in such a moving chart related to variations in a fixed chart? It turns out that they differ by a Lie derivative.

Consider first the simplest case - the variation of a scalar field φ. It is clear that the variation $\delta^w\varphi$ of the field at a given grid point of a chart w, is related to its variation $\delta^F\varphi$ at the corresponding grid point of a coordinate system x^μ that is fixed in the manifold via

$$\delta^w\varphi = \delta^F\varphi + \delta^w x^\mu \partial_\mu \varphi. \tag{121}$$

The variations of the x coordinates at a w chart grid point defines a vector $v = \delta^w x^\mu \partial_\mu$ which may be thought of as the variation of the position of the w grid point in the manifold. Thus

$$\delta^w\varphi = \delta^F\varphi + d_v\varphi. \tag{122}$$

A similar relation holds for the variations of tensor fields, such as the metric g, in the w chart:

$$\delta^w g = \delta^F g + \pounds_v g. \tag{123}$$

Here $\delta^w g$ is the tensor field with w components equal to the variation δ of the w components of g at fixed values of the w coordinates. That is

$$[\delta^w g]_w = \delta[g]_w \tag{124}$$

where $[g]_w$ indicates the w components of g expressed as functions of the w coordinates. Notice that if w' is a chart which moves together with w, i.e. the mapping between the charts is field independent, then $\delta^{w'} = \delta^w$ on tensors. In other words, what is important is not the chart but how it moves when the field is changed.

These results generalize to any field X that has well defined components in any C^∞ chart. In the possibly field dependent chart w the components of $\delta^w X$ are just the variations of the w components $[X]_w$ of X. To define the components of $\delta^w X$ in another we impose the requirement that, just as for tensors, the variation $\delta^u X$ in a co moving chart u be equal to $\delta^w X$. Specifically, suppose w_0 is the w chart corresponding to the fiducial field configuration we are varying about, and u_0 is another chart. Then $u_0 \circ w_0^{-1}$ is the (field independent) diffeomorphism that maps the w_0 chart to the u_0 chart, $u = u_0 \circ w_0^{-1} \circ w$ is a chart co-moving with w that coincides with u_0 at the fiducial field configuration, and

$$[\delta^w X]_{u_0} = [\delta^u X]_{u_0} = \delta[X]_u. \tag{125}$$

With this definition $\delta^w = \delta^F + \pounds_v$ quite generally.[58] Suppose δ is the tangent $d/d\alpha$ to a family of configurations of the gravitational field parametrized by $\alpha \in \mathbb{R}$, with

[58] The general formalism is presented mostly for the sake of completeness. The reader may find it easier to deduce the form of $\delta^w X$ for each field X that is needed directly from the definition (125). The fields of interest, aside from four dimensional tensors, will be Christoffel symbols and the BFC data.

$\alpha = 0$ at the fiducial solution. Let X_α be the corresponding family of X fields, w_α be the corresponding w charts, ϕ_α the family of diffeomorphisms mapping w_0 to w_α, v the vector field generating ϕ_α, and ϕ^0_α the mapping induced by ϕ_α on the components of X, i.e. $[X]_{w_\alpha} = \phi^0_\alpha[[X]_{w_0}]$. Then

$$[\delta^w X]_{w_0} \equiv \frac{d}{d\alpha}[X_\alpha]_{w_\alpha}|_{\alpha=0} \tag{126}$$

$$= \frac{d}{d\alpha}\phi^0_\alpha[[X_\alpha]_{w_0}]|_{\alpha=0} = [\delta^F X]_{w_0} + \frac{d}{d\alpha}\phi^0_\alpha[[X_0]_{w_0}]|_{\alpha=0} = [[\delta^F + \pounds_v]X]_{w_0} \tag{127}$$

The equation $d\,\phi^\circ_\alpha[X_0]_{w_0}/d\alpha|_{\alpha=0} = [\pounds_v X]_{w_0}$ is the natural generalization of the definition of the Lie derivative for tensors (see [Wald84] Appendix C, but note that ϕ^* there is the inverse of our ϕ°). It defines $\pounds_v$ to be the generator of the action of the family of diffeomorphisms ϕ_α on X.

The relation between the variations of components in differently moving charts is entirely analogous to that between variations in fixed and moving charts. For instance the variations of a and b components are related by

$$\delta^b = \delta^a + \pounds_\xi, \tag{128}$$

where ξ is the difference of the v fields associated with the a and b charts. ξ can be evaluated in the a chart by applying (128) to the a coordinates themselves:

$$\delta^b a^\alpha = 0 + \pounds_\xi a^\alpha = \xi^\alpha, \tag{129}$$

and in the b chart by applying it to the b coordinates:

$$\xi^\mu = -\delta^a b^\mu. \tag{130}$$

To lighten the notation the superscript indicating the chart relative to which a variation is taken will often be dropped. When no chart is indicated the variation of a field is to be taken with respect to its "natural chart". The natural chart of a field component (of a tensor or any other multi-component field) is the chart that the component is referred to. For instance $\delta g_{\mu\nu}$, with $g_{\mu\nu}$ the components of the metric in a fixed chart, is $\delta^F g_{\mu\nu}$. The BFC data, and the variants we have discussed, each have a corresponding natural chart: $e_{A\,ij}$, $r_{A\,0}$, and f^a_A all have natural chart a_A. ρ_0, χ, ω_a, and s^i_A have natural chart b. Note that s^i_A is not an a_A vector components, but a scalar function of the θ^a. Similarly f^a_A is a scalar function of the y_A. The natural chart of e_{ab} is of course b. Finally, we adopt the convention that the natural chart of a coordinate is the chart it forms part of. Thus $\delta a^\alpha \equiv \delta^a a^\alpha = 0$ and $\delta b^\Lambda \equiv \delta^b b^\Lambda = 0$.

Although the b chart is clearly a moving chart, being adapted to the generators of $\mathcal{N}$, one may, when solving (53) for the auxiliary pre-Poisson bracket, restrict attention

to variations of the solution that leave the b^μ fixed in a neighbourhood of S_0, where the data referred to the b chart live: (53) requires that for any initial datum φ on the interior of $\mathcal{N}$

$$\delta\theta = \bar{\Omega}[\{\varphi, \cdot\}_*, \delta] \tag{131}$$

for all δ which satisfy the linearized field equations and vanish in a neighbourhood of $\partial\mathcal{N}$. The right side of this equation is unchanged by the addition to either argument of $\bar{\Omega}$ of a diffeomorphism generator $\pounds_\tau$ vanishing near $\partial\mathcal{N}$ since such a generator is a degeneracy vector of $\bar{\Omega}$. Moreover, if φ is a BFC datum the left side is also invariant under the addition of such a term to δ. Now, if φ is a BFC datum living at a point $p \in int\mathcal{N}$ then $\{\varphi, \cdot\}_*$ acts only on the data on the generator through p, thus leaving the b^μ invariant in a neighbourhood of $\partial\mathcal{N} - S_L - S_R$. As explained in subsection 3.3, δ also leaves the b^μ invariant in a neighbourhood of $\partial\mathcal{N} - S_L - S_R$. The (linearized) diffeomorphisms induced by $\{\varphi, \cdot\}_*$ and δ can thus be cancelled near S_0 by diffeomorphism generators that vanish in a neighbourhood of $\partial\mathcal{N}$.

Note that the pair of charts a_R and a_L cannot both be held fixed on S_0 in the same manner as the b chart because the transformation from the a_R chart to the a_L chart depends on the fields.

3.5 Freeness and completeness of the BFC and CF data

To show that the BFC data of section 3 is free (apart from the constraint (109)) and complete it is sufficient to show that any BFC data determines a set of Sachs data such that a solution matches the CF data iff it matches the Sachs data. Since we assume that any Sachs data determines a unique solution, modulo diffeomorphisms, the same would also be true for the BFC data. Furthermore, since the CF data are equivalent to the BFC data, this would establish that the CF data are also complete and completely free.

The BFC data, the CF data, and the Sachs data are all explicit coordinate representations of the geometrical initial data defined in subsection 3.2 - the 3-metric on $\mathcal{N}$ and χ and ω on S_0 - but referred to different coordinate systems. The BFC data is

in part referred to the b chart and in part to the a charts, the CF data refers to the b chart, and the Sachs data refers to essentially the b chart, but with affine parameters of the generators in the solution spacetime replacing the area parameters $v^\pm$.[59] The key point to be demonstrated is thus that the different data sets contain

[59] Sachs also uses a special chart, adapted to the geometry, on S_0 - essentially the ψ chart defined in subsection 3.3. But this specialization of the chart on S_0 plays no role in the results of Sachs and Rendall on the existence and uniqueness of solutions, so we may as well use the θ chart on S_0 to define Sachs' data.

sufficient information to define the map to the coordinate system of the other data sets.

The BFC and the CF data each define the transformation (113,114) from the a chart on a branch of $\mathcal{N}$ to the b chart on that branch. In particular they define the map from the coordinates y^i on each branch to the coordinates θ^a. This allows one to compute the CF data corresponding to a spacetime metric from the BFC data, and *vice versa*, establishing the equivalence of the these two data sets.

It remains to show that the BFC data define the map from the b chart to Sachs' coordinates, in particular the map from the area parameter r to an affine parameter η (and thus also from $v = r/r_0$ to η). In a non degenerate Lorentzian solution matching the BFC data the generators of $\mathcal{N}$ are geodesics: The degeneracy vectors of the degenerate 3-metric defined by the BFC data are orthogonal to all tangents to $\mathcal{N}$ and null, so $\mathcal{N}$ is a null hypersurface and the degeneracy vectors are its normals - from which it follows that the integral curves of the degeneracy vectors are null geodesics (see prop. B.3 of appendix B). Now if η is an affine parameter of a generator then the corresponding tangent vector $k = \partial_\eta$ is parallel transported along the generator: $\nabla_k k = 0$. In a coordinates this equation is equivalent to

$$\Gamma^r_{rr} = \frac{d}{dr} \log \frac{d\eta}{dr}. \tag{132}$$

But on $\mathcal{N}$ the field equation $G_{rr} = 0$ is equivalent to

$$\Gamma^r_{rr} = -\frac{r}{8} \partial_r e^{ij} \partial_r e_{ij}. \tag{133}$$

(see Appendix D.) Combining these equations one obtains the relation

$$\frac{d}{dr} \log \frac{d\eta}{dr} = -\frac{r}{8} \partial_r e^{ij} \partial_r e_{ij}, \tag{134}$$

which may be integrated using BFC data to obtain η as a function of r up to an additive constant and a constant factor on each generator in concordance with the freedom to change affine parameters by affine transformations. (The "constants" are independent of r, but may depend on y.) Of course η obtained in this way is not actually an affine parameter. Only when the field equation $G_{rr} = 0$ holds does (134) imply (132), making η is an affine parameter of the spacetime geometry.

Sachs sets the affine parameters, η_L and η_R, of the two congruences of generators to zero on S_0. To partly fix the normalization of the affine parameters he also demands that $\partial_{\eta_L} \cdot \partial_{\eta_R} = -1$ on S_0. The remaining freedom in the normalization of the generators can be fixed in our case by requiring

$$d\eta_R / dv^- = 1 \tag{135}$$

on S_0. Then, by (117),

$$d\eta_L/dv^+ = -\chi_v. \tag{136}$$

The BFC data determine the a coordinate components of the 3-metric on $\mathcal{N}$, and also, as we have just seen, the transformation to Sachs' coordinates on $\mathcal{N}$. They therefore determine the 3-metric of $\mathcal{N}$ in Sachs' coordinates. This determines most of the Sachs data.

The Sachs data consists of the conformal 2-metric, $e_{ab}(\eta, \theta)$, as a function of Sachs' coordinates on each branch of $\mathcal{N}$ and four fields on S_0, referred to the coordinates θ^a: the area density $\rho(\theta)$ and its derivatives $\partial_{\eta_L}\rho$ and $\partial_{\eta_R}\rho$, and ω_η, the normalized twist ω corresponding to the parametrizations η_L and η_R of the generators.[60] All but the last of these are subsumed in the 3-metric of $\mathcal{N}$.[61] [62]

The final Sachs datum, ω_η, is related to, ω_v, the normalized twist corresponding to the parametrizations v^+ and v^- of the generators via

$$\omega_{\eta\, a}(\theta) = \omega_{v\, a}(\theta) - \partial_a \log \chi_v(\theta). \tag{140}$$

(See (98), (136) and (135).)

Any solution matching the BFC data necessarily also matches these Sachs data. Since the solution is uniquely determined by the Sachs data it is uniquely determined by the BFC data.[63] Thus the BFC data are complete.

---

[60] Sachs actually takes as his final data a pair of quantities he writes as $C_{A,1} \quad A = 1, 2$. However these are just the θ coordinate components of the 1-form $-\omega_\eta$. This can be seen most easily from his equation (19), which when a forgotten factor of $1/2$ is restored and it is rewritten in our notation reads

$$\frac{1}{2} C_{a,1} = \partial_{\eta_L} \cdot \nabla_a \partial_{\eta_R}. \tag{137}$$

This equation, the normalization $\partial_{\eta_L} \cdot \partial_{\eta_R} = -1$ on S_0, and the expression (100) imply the claim.

[61] The explicit relations of these data with the BFC data are not complicated. Since the 3-metric on $\mathcal{N}$ is degenerate the induced 2-metric at a point on a constant η section of $\mathcal{N}$ is the same as the induced 2-metric on the constant r section at the same point. Thus the e_{ab} at a point are determined by the e_{ij} at that point and the standard tensor density transformation associated with the transformation from y to θ coordinates. $\rho(\theta)$ is both a Sachs and BFC datum, and the derivatives of ρ are fixed by the normalization conditions (136) and (135) on the η parameters:

$$\partial_{\eta_L}\rho = 2\rho\, dv^+/d\eta_L = -2\rho/\chi_v \tag{138}$$

$$\partial_{\eta_R}\rho = 2\rho\, dv^-/d\eta_R = 2\rho. \tag{139}$$

[62] In the coordinate independent description of the data in subsection 3.2 a further datum, χ, is specified on S_0, but this is identically equal to -1 for the parametrization η_L, η_R of the generators.

[63] It has been proved that the Sachs data determine the spacetime metric uniquely up to diffeomorphisms in a neighbourhood of S_0 in $\underline{\mathcal{D}}$ [Ren90], and we are assuming that they in fact determine a maximal Cauchy development of $\mathcal{N}$. This implies that the components of the metric in Sachs'

The BFC data are also free, aside from the one constraint (109). This follows from the fact that, firstly, any BFC data that satisfies (109) defines Sachs data, and secondly, that the solution corresponding to this Sachs data really matches all the original BFC data. To verify the second claim consider first the area parameter r', defined like r but from the 3-metric induced on $\mathcal{N}$ by the solution. r', like r, must satisfy (134) which may be re-expressed as

$$\frac{d^2 r}{d\eta^2} = r\kappa(\eta), \tag{141}$$

with $\kappa = \frac{1}{8}\partial_\eta e^{ij}\partial_\eta e_{ij}$ a function of η that is determined by the Sachs data and is thus the same for the original 3-metric as for the 3-metric induced by the solution. The solution to this linear second order equation is completely determined by the value of $d\log r/d\eta$ at S_0 and the value of r at the other end of the generator. At S_A $r'_A = r_A = 1$ by definition, and at S_0 $d\log r_A/d\eta_A = d\log r'_A/d\eta_A = 1/2 d\log\rho/d\eta_A$ since this is part of the Sachs data defined by the original BFC data. Thus $r'_A = r_A$, and, since $r(\eta)$ and the Sachs data determine the 3-metric completely (without use of the field equations), the 3-metric induced from the solution is equal to the original 3-metric. The 3-metric BFC data induced by the solution are thus the same as the original ones. Since $v' \equiv r'/r'_0 = v$ it is also clear that the remaining BFC data, χ_v and ω_v, induced by the solution are equal to the ones originally specified.

4 The presymplectic 2-form

4.1 Preliminaries

The auxiliary pre-Poisson bracket $\{\cdot,\cdot\}_*$ on functions of the initial data is defined by the requirements that it should reproduce the Peierls bracket on observables, be antisymmetric, that it be causal in the sense that the bracket vanishes between data at points that cannot be connected by any causal curve, and that it respects any constraints that the data must satisfy. As shown in section 2, $\{\cdot,\cdot\}_*$ reproduces the Peierls bracket on observables iff for any initial datum θ on $int\mathcal{N}$

$$\delta_0\theta = \bar{\Omega}[\{\theta,\cdot\}_*, \delta_0] \tag{142}$$

for all δ_0 which vanish in a neighbourhood of $\partial\mathcal{N}$.

spacetime coordinates are uniquely determined. Sachs' spacetime coordinates are obtained from the b coordinates by replacing the coordinates $v^\pm$ by η_L and η_R, everywhere given by the same functions of v^+ and v^- respectively as on $\mathcal{N}$. Thus the Sachs data define the solution in b coordinates uniquely as well.

In this and the following section $\bar{\Omega}[\delta_1, \delta_2]$ will be evaluated explicitly in terms of the BFC initial data defined in subsection 3.3 for variations δ_1 and δ_2 in a class that is wide enough to include all δ_0 allowed in (142) and a solution $\{\theta, \cdot\}_*$ to (142). Specifically $\bar{\Omega}[\delta_1, \delta_2]$ will be calculated for δ_1 and δ_2 satisfying the following conditions on each branch $\mathcal{N}_A$ of the initial data hypersurface:

a) The variation $v_A^\alpha = -\delta^F a_A^\alpha$ of the adapted coordinates a_A^α corresponding to $\mathcal{N}_A$ vanishes in a *neighbourhood* of $\partial\mathcal{N} \cap \mathcal{N}_A$.

b) The variation $\delta\bar{\rho}_A$ of the area density $\bar{\rho}_A$ on the truncating 2-surface S_A (where the generators of $\mathcal{N}_A$ cross the boundary $\partial\mathcal{N}$) vanishes.

These conditions are clearly satisfied by the variations δ_0 in (142) because they vanish near $\partial\mathcal{N}$. On the other hand, the variation $\{\theta, \cdot\}_*$ generated by an initial datum θ is not in general expected to vanish on all of $\partial\mathcal{N}$. However, recall that (142) determines $\{\theta, \cdot\}_*$ only up to the addition of an arbitrary diffeomorphism generator $\pounds_\eta$ (a generalized degeneracy vector of $\bar{\Omega}$). It turns out that for any bracket satisfying (142), and the causality condition, there exist suitable diffeomorphism generators such that the modified bracket obtained by adding these to the original bracket satisfies a) and b).

Let us verify this in detail. The requirement that the auxiliary pre-Poisson bracket be causal implies that the variation $\{\phi(p), \cdot\}_*$ generated by the value of an initial data field ϕ at the point $p \in \mathcal{N}$ can be non-zero only on the generators passing through p. Since all our initial data live on the interior of $\mathcal{N}$ this implies that the variation generated by any initial datum vanishes in some neighbourhood of $\partial\mathcal{N} - S_R - S_L$. But it would seem that the conditions a) and b) could be violated at some points in the interior of S_L and/or S_R.

In order to work with smooth variations let us smear the initial data fields with smooth test functions. Thus, instead of taking θ to be the value of an initial data field at an interior point of $\mathcal{N}$ we take θ to be the integral, weighted by a smooth test function with support contained in $int\mathcal{N}$, of such an initial data field. Imposing (142) for all such test functions implies that it holds distributionally for the initial data themselves, which is all we will ultimately require.

Now suppose that $\{\theta, \cdot\}'_*$ is a solution to (142). By hypothesis, the area density ρ transverse to a generator always increases or decreases along the generator - it is never stationary - in the spacetime geometry and for the $\mathcal{N}$ we are considering. Therefore if an infinitesimal variation of the geometry changes the area density at a point this change can always be cancelled by a suitable infinitesimal displacement along the generator. By adding the diffeomorphism generator $\pounds_\eta$ to $\{\theta, \cdot\}'_*$ with η taken parallel to the generators and with

magnitude such that $d_\eta \rho = -\{\theta, \rho\}'_*$ on S_L and S_R one may ensure that the area density on these surfaces is invariant under the combined variation. That is, condition b) is satisfied.

What about condition a)? The modified action $\{\theta, \cdot\}'_* + \pounds_\eta$ of θ will in general affect the generator passing through a given (interior) point of S_A. Since the generator is identified by its point of intersection with S_A this point remains fixed by definition, but all other points on the generator will in general be displaced, inducing non-zero changes in the adapted coordinates a^α arbitrarily close to S_A in violation of requirement a). These changes in the a^α can clearly be undone in neighbourhoods of S_L and S_R by adding a second diffeomorphism generator, $\pounds_{\eta'}$, with η' chosen to vanish on S_L and S_R so it does not affect $\bar{\rho}$ and b) remains satisfied. Furthermore, the original variation of the generators must vanish outside the causal domain of influence of the support of the smearing function of θ, and thus in a neighbourhood of $\partial\mathcal{N} - S_L - S_R$, which implies that the action of θ, with the two added diffeomorphism generators, leaves the adapted coordinates invariant in a neighbourhood of all of $\partial\mathcal{N}$. That is, $\{\theta, \cdot\}'_* + \pounds_\eta + \pounds_{\eta'}$ is a solution to (142) satisfying conditions a) and b) above. We may therefore solve (142) for $\{\theta, \cdot\}_*$ assuming a) and b) hold (and then recover all the remaining solutions by adding diffeomorphism generators to the first solution).

One consequence of condition b) is worth noting. $r_{0\,L}$, $r_{0\,R}$, and ρ_0 are *a priori* independent BFC data but, because $\bar{\rho}_A(y) = \rho_0(f_A(y)) r_0(y)^{-2} \det[\partial_i f^a_A]$ is invariant under the class of variations being considered, the variations $\delta r_{A\,0}$ may always be reduced to variations of other BFC data. We shall do this and variations of $r_{0\,A}$ will not appear in the expression for the presymplectic 2-form finally used to solve for the auxiliary bracket between the data. This does not mean that the brackets of the $r_{0\,A}$ are undetermined. Since the variation $\{\theta, \cdot\}_*$ satisfies b) by the very argument we have just given $\{\theta, r_{A\,0}\}_*$ can be expressed in terms of the the brackets of θ with other data. It is not difficult to do so explicitly and the reader may do so using the brackets between the remaining BFC data given further on.

In the next subsection the symplectic potential $\Theta[\delta]$ will be evaluated in terms of the BFC data for δ satisfying conditions a) and b). Then, in the following subsection, the expression for Θ obtained will be used to compute $\bar{\Omega}$ in terms of the same data for variations satisfying a) and b). The solution of the resulting explicit form of equation (142), which yields the auxiliary pre-Poisson brackets between the initial data, is left to section 5.

4.2 Calculation of the symplectic potential in terms of the almost free BFC initial data

We shall calculate explicitly only the part of the symplectic potential corresponding to the branch $\mathcal{N}_R$, denoted Θ_R. Since the two branches of $\mathcal{N}$ enter the problem on an exactly equal footing, $\mathcal{N}_L$ contributes an entirely analogous expression.

Θ_R is just the contribution of $\mathcal{N}_R$ to the boundary term (19) in the variation of the action integral (on a region of which $\mathcal{N}_R$ forms part of the boundary). That is

$$\Theta_R[\delta] = -\frac{1}{8\pi G}\int_{\mathcal{N}_R} \delta\Gamma^{[\sigma}_{\sigma\nu} g^{\mu]\nu}\sqrt{-g}\, d\Sigma_\mu, \tag{143}$$

in terms of field components and their variations referred to manifold fixed coordinates.

Recall that the BFC data on $\mathcal{N}_R$ consist of bulk data, namely the conformal 2-metric components in the a coordinates, specified on all of $\mathcal{N}_R$, and surface data associated with the 2-surface S_0. The contributions to $\Theta_R[\delta]$ of the variations of the bulk data e_{ij} and of the surface data on S_0 can be neatly separated by expressing the variation of the metric as the sum of a contribution due to the variation of its components with respect to the a coordinates corresponding to to the R branch, and another due to the variation of these a coordinates themselves (with respect to fixed coordinates).

That is, we decompose Θ_R according to

$$\Theta_R[\delta] = \Theta_R[\delta^a] - \Theta_R[\pounds_v], \tag{144}$$

where v is the vector field $-\delta^F a^\alpha \partial_\alpha$. The first term can be written immediately in terms of a coordinate components, and reduces to an integral over $\mathcal{N}_R$ of a functional of e_{ij} and its variation. The second term turns out to be a surface integral over S_0 and depends on the data on S_0 and their variations (as well as on the derivative of e_{ij} along the generators at S_0).

In direct analogy with (79)

$$\Theta_R[\pounds_v] = -\frac{1}{16\pi G}\int_{\partial\mathcal{N}_R} \nabla^\mu v^\nu \sqrt{-g}\, d\Sigma_{\mu\nu}. \tag{145}$$

By condition a) on the variation we are considering v vanishes in a neighbourhood of $\partial\mathcal{N}_R - S_0 = \partial\mathcal{N} \cap \mathcal{N}_R$, so

$$\Theta_R[\pounds_v] = \frac{1}{16\pi G}\int_{S_0} \nabla^\mu v^\nu \sqrt{-g}\, d\Sigma_{\mu\nu}. \tag{146}$$

(The sign reflects the orientation of S_0 which is taken to be opposite to that of $\partial\mathcal{N}_R$.)

As discussed in subsection 3.4 one may restrict attention to variations such that the b chart is fixed in the manifold in a neighbourhood of S_0 in $\mathcal{N}$. Then $v = -\xi$ on S_0, where ξ is defined by $\delta^a = \delta^b - \pounds_\xi$. That the substitution of v by $-\xi$ does not affect the symplectic potential may be verified directly using (146): The entire symplectic potential, obtained by summing the contributions of the two branches of $\mathcal{N}$, is

$$\Theta[\delta] = \Theta_R[\delta^{a_R}] + \Theta_L[\delta^{a_L}] + \frac{1}{16\pi G}\int_{S_0} \nabla^\mu [v_L - v_R]^\nu \sqrt{-g}\, d\Sigma_{\mu\nu}. \tag{147}$$

As in (146) the orientation of S_0 is opposite to that of $\partial\mathcal{N}_R$, and thus equal to that of $\partial\mathcal{N}_L$. Now since $\delta^b = \delta + \pounds_{v_b}$ and $\delta^{a_A} = \delta + \pounds_{v_A}$, $\xi_A = -v_A + v_b$. That is, ξ_A differs from $-v_A$ by a vector field v_b that does not depend on the branch A. It follows that $v_L - v_R = -(\xi_L - \xi_R)$. We will therefore take

$$\Theta_R[\delta] = \Theta_R[\delta^a] + \Theta_R[\pounds_\xi] = \Theta_R[\delta^a] + \frac{1}{16\pi G}\int_{S_0} \nabla^\mu \xi^\nu \sqrt{-g}\, d\Sigma_{\mu\nu}. \tag{148}$$

as the contribution of $\mathcal{N}_R$ to $\Theta[\delta]$. We will also use the conceptual crutch of supposing the b chart to be fixed near S_0 under the variations being considered, so $\delta^b = \delta$ on fields there. This condition does not contradict conditions a) and b) on the variations, since these conditions refer only to what happens near S_L and S_R, whereas the diffeomorphism generator that must be added to the variations to keep the b chart fixed near S_0 may be chosen to have support in a closed neighbourhood[64] of S_0 excluding S_L and S_R.

In terms of the b coordinates the pullback to S_0 of $\sqrt{-g}\, d\Sigma_{\Lambda\Upsilon}$ is

$$\sqrt{-g}\, \underline{\underline{d\Sigma}}_{\Lambda\Upsilon} \equiv \frac{1}{2}\sqrt{-g}\, \varepsilon_{\Lambda\Upsilon\Xi\Pi}\, \underline{\underline{db}}^\Xi \wedge \underline{\underline{db}}^\Pi \tag{149}$$

$$= -2\,\rho_0 \chi\, \partial_{[\Lambda} v^+\, \partial_{\Upsilon]} v^-\, \underline{\underline{d\theta}}^1 \wedge \underline{\underline{d\theta}}^2. \tag{150}$$

Since v^+ and v^- are constant on $\mathcal{N}_R$ and $\mathcal{N}_L$ respectively dv^+ and dv^- must be proportional to the normals n_- and n_+ respectively.[65] In fact, since $d_{n_+} v^+ = d_{n_-} v^- = 1$ it follows that $n_\pm = \chi dv^\mp$. Hence

$$\sqrt{-g}\, \underline{\underline{d\Sigma}}_{\Lambda\Upsilon} = -\frac{2}{\chi}\, n_{-\,[\Lambda}\, n_{+\,\Upsilon]}\, \epsilon \tag{151}$$

where $\epsilon = \rho_0\, d\theta^1 \wedge d\theta^2$ is the area 2-form on S_0.

Substituting this form into (146) yields

$$\Theta_R[\pounds_\xi] = \frac{1}{16\pi G}\int_{S_0} \epsilon\, \frac{1}{\chi}\{n_- \cdot \nabla_{n_+}\xi - n_+ \cdot \nabla_{n_-}\xi\}. \tag{152}$$

[64] The closure of an open neighbourhood of S_0.

[65] Recall that the tangents to the generators $n_- \equiv \partial_{v^-}$ are normal to $\mathcal{N}$ by prop. B.2.

The derivative along n_+ may be eliminated in favour of a variation of χ:

$$\delta\chi = \delta g_{+-} = [\delta^a g]_{+-} + \pounds_\xi g_{+-} \tag{153}$$
$$= \partial_{v^+} a^\alpha \partial_{v^-} a^\beta \delta g_{\alpha\beta} + 2 n_+^\mu n_-^\nu \nabla_{(\mu}\xi_{\nu)}. \tag{154}$$

But $\partial_{v^-} a^\beta = r_0 \delta^\beta_r$, and (by (103)) $g_{\alpha r} = -\delta^u_\alpha$, which is constant, so $[\delta^a g]_{+-} = 0$ and

$$\delta\chi = n_+ \cdot \nabla_{n_-}\xi + n_- \cdot \nabla_{n_+}\xi. \tag{155}$$

The integrand of (152) is thus equal to

$$\epsilon \frac{1}{\chi}[\delta\chi - 2 n_+ \cdot \nabla_{n_-}\xi]. \tag{156}$$

Under the variations being considered u remains zero on $\mathcal{N}_R$.[66] ξ is thus tangent to $\mathcal{N}_R$ and can be expanded as

$$\xi = \xi_\perp + \xi^- n_-, \tag{157}$$

where ξ^- is the v^- component of ξ and $\xi_\perp$ is tangent to the $v^- = \textit{constant}$ cross sections of $\mathcal{N}_R$.

$\xi_\perp$ generates the variations of the y coordinates at fixed θ on the $v^- = \textit{constant}$ surfaces induced by the variation of the metric. That is, $\pounds_{\xi_\perp} y^i = \delta^b y^i$. Now by definition the curves $y^i = \textit{constant}$ and $\theta^a = \textit{constant}$, always coincide with the generators, a fact which the displacement of the a chart with respect to the b chart induced by a variation of the metric must respect. That is, the constant y^i curves must always remain tangent to the vector field $\partial_{v^-} = n_-$. Thus $\pounds_{n_-} y^i = \partial_{v^-} y^i = 0$ and $\pounds_{n_-}\delta^b y^i = \delta^b \partial_{v^-} y^i = 0$. It follows that

$$\pounds_{[n_-,\xi_\perp]} y^i = [\pounds_{n_-}\pounds_{\xi_\perp} - \pounds_{\xi_\perp}\pounds_{n_-}] y^i = 0. \tag{158}$$

Clearly also $\pounds_{[n_-,\xi_\perp]} v^\pm = 0$, so

$$[n_-, \xi_\perp] \equiv \pounds_{n_-}\xi_\perp = 0. \tag{159}$$

The second term in (156) may therefore be expanded as

$$2 n_+ \cdot \nabla_{n_-}\xi = 2 n_+ \cdot \nabla_{n_-}[\xi_\perp + \xi^- n_-] = 2\chi d_{n_-}\xi^- + 2\xi^- n_+ \cdot \nabla_{n_-} n_- + 2 n_+ \cdot \nabla_{\xi_\perp} n_- \tag{160}$$

Let us consider each term in turn, beginning with the last. From the definition (118) of ω

$$2 n_+ \cdot \nabla_{\xi_\perp} n_- = d_{\xi_\perp}\chi + \chi \xi^a_\perp \omega_a. \tag{161}$$

[66] In the definition of the space of solutions $\mathcal{S}$ and the space of solutions to the linearized field equations it is required that $\mathcal{N}$ always remains null.

The middle term is a little more subtle. Since n_- is tangent to a geodesic and $n_- = \partial_{v^-} = r_0 \partial_r$

$$n_+ \cdot \nabla_{n_-} n_- = n_+ \cdot r_0^2 \nabla_{\partial_r} \partial_r = n_+ \cdot r_0 \Gamma^r_{rr} n_- = \chi r_0 \Gamma^r_{rr}. \tag{162}$$

Γ^r_{rr} can be expressed in terms of the BFC data by means of one of the field equation (we are working in the space of solutions) - see (133) and Appendix D. However this will not be necessary since the term we are considering, together with another that we will find further on, constitute a total variation which may be subtracted off from Θ without altering the presymplectic 2-form.

It remains to express ξ^- and $d_{n_-}\xi^-$ in terms of the BFC data and their variations. ξ^- turns out to measure the variation of $r_0(y)$. Define

$$\delta^y = \delta^b - \pounds_{\xi_\perp}. \tag{163}$$

(Since $\delta^b y^i = \xi^i_\perp$ this is the variation associated with the hybrid moving coordinate system (v^+, v^-, y^1, y^2).) On $\mathcal{N}_R$ the variation of r at fixed v^- and y^i is then

$$\delta^y r \equiv \delta^b r - \pounds_{\xi_\perp} r = \delta^a r + \pounds_{\xi^- n_-} r = \xi^- \partial_{v^-} r = \xi^- r_0. \tag{164}$$

Hence $\xi^- = \delta^y r / r_0 = v^- \delta^y \log r_0$. On S_0 therefore

$$\xi^- = d_{n_-}\xi^- = \delta^y \log r_0 = \frac{1}{2}\delta^y \log \rho_y, \tag{165}$$

or equivalently

$$\epsilon \xi^- = \epsilon d_{n_-}\xi^- = \frac{1}{2}\delta^y \epsilon, \tag{166}$$

where $\delta^y \bar{\rho} = 0$, which follows from condition b) on δ, has been used.

Substituting all these results into (152) we find

$$\Theta_R[\pounds_\xi] = -\frac{1}{16\pi G}\int_{S_0} \epsilon(\delta^y \lambda + \xi^a_\perp \omega_a) + \delta^y \epsilon (1 + r_0 \Gamma^r_{rr}), \tag{167}$$

where $\lambda = -\log|\chi|$.

Now let us turn to the first term in (144), $\Theta_R[\delta^a]$. In working with this quantity it is convenient to use the a coordinates, because in these coordinates the a variation, δ^a, of a field reduces to simply the variation, at fixed a^α, of the a coordinate components of the field. For instance

$$[\delta^a \Gamma]^\alpha_{\beta\gamma}(a) = \delta \Gamma^\alpha_{\beta\gamma}(a) \tag{168}$$

Thus we may write

$$\Theta_R[\delta^a] = -\frac{1}{8\pi G}\int_{\mathcal{N}_R} \delta \Gamma^{[\alpha}_{\alpha\gamma} g^{\beta]\gamma} \sqrt{-g}\, d\Sigma_\beta. \tag{169}$$

In a coordinates the components of the metric on $\mathcal{N}_R$ are (by (103))

$$g_{\alpha\beta} = \begin{bmatrix} 0 & -1 & \\ -1 & 0 & \\ & & h_{ij} \end{bmatrix}, \quad g^{\alpha\beta} = \begin{bmatrix} 0 & -1 & \\ -1 & 0 & \\ & & h^{ij} \end{bmatrix}, \tag{170}$$

with h^{ij} the inverse of h_{ij}. Thus $\sqrt{-g} = \sqrt{det[h_{ij}]} \equiv \rho_y$ and the pull back to $\mathcal{N}_R$ of $\sqrt{-g}\, d\Sigma_\beta$ is

$$\sqrt{-g}\, \underleftarrow{d\Sigma}_\beta = \rho_y \delta^u_\beta\, \underleftarrow{dy}^1 \wedge \underleftarrow{dy}^2 \wedge \underleftarrow{dr} = \delta^u_\beta\, \underleftarrow{\epsilon} \wedge \underleftarrow{dr}. \tag{171}$$

(A $\underleftarrow{\ }$ beneath a form indicates that the form is pulled back to $\mathcal{N}$.)

The integrand in (169) thus reduces to

$$\begin{aligned} \delta\Gamma^{[\alpha}_{\alpha\gamma} g^{u]\gamma} \epsilon \wedge dr &= \frac{1}{2}\{-\delta\Gamma^\alpha_{\alpha r} + g^{\alpha\gamma}\delta\Gamma_{r\alpha\gamma}\}\epsilon \wedge dr & (172)\\ &= -\frac{1}{2}\{\delta\partial_r \log\sqrt{-g} + 2\delta\Gamma_{rur} - h^{ij}\delta\Gamma_{rij}\}\epsilon \wedge dr & (173)\\ &= -\frac{1}{2}\{\delta\partial_r \log\rho_y + \delta\partial_u g_{rr} + \frac{1}{2}h^{ij}\delta\partial_r h_{ij}\}\epsilon \wedge dr & (174) \end{aligned}$$

Now recall that $\rho_y(y,r) = r^2\bar{\rho}(y)$, where $\bar{\rho}$ is the area density on S_R. Thus for the variations we are considering, which leave $\bar{\rho}(y)$ invariant, $\delta\rho_y = 0$. As a consequence

$$\delta\partial_r \log\rho_y = 0 \tag{175}$$

and

$$\frac{1}{2}\delta[\partial_r h_{ij}]h^{ij} = \delta\partial_r \log\rho_y - \frac{1}{2}\partial_r[\rho_y\, e_{ij}]\delta\frac{e^{ij}}{\rho_y} = -\frac{1}{2}[\partial_r e_{ij}]\delta e^{ij}. \tag{176}$$

(Here e^{ij} is the inverse of e_{ij} and the fact that $e_{ij}\delta e^{ij} = -\delta \log \det[e_{ij}] = 0$, has been used.)

The remaining, middle, term in (174) is proportional to $\delta\Gamma^r_{rr}$, since on $\mathcal{N}_R$

$$\partial_u g_{rr} = 2\Gamma^r_{rr}. \tag{177}$$

Substituting (175), (176) and (177) into (174) yields an expression for $\Theta_R[\delta^a]$ in terms of the BFC data and Γ^r_{rr}, and their variations. Adding to this the expression (167) for $\Theta_R[\pounds_\xi]$ we obtain

$$\begin{aligned} \Theta_R[\delta] &= -\frac{1}{16\pi G}\Big\{ \int_{S_R} \epsilon \int_{r_0}^1 \frac{1}{2} r^2 \partial_r e_{ij}\delta e^{ij} - 2r^2\delta\Gamma^r_{rr} dr \\ &\quad + \int_{S_0} \epsilon(\delta^y\lambda + \xi^a_\perp\omega_a) + \delta^y\epsilon(1 + r_0\Gamma^r_{rr})\Big\} \end{aligned} \tag{178}$$

Here the identity

$$\int_{\mathcal{N}_R} f\epsilon \wedge dr = \int_{S_R} \epsilon \int_{r_0}^{1} r^2 f dr, \tag{179}$$

valid for any function f on $\mathcal{N}_R$, has been used to turn the integral over $\mathcal{N}_R$ into an integral over each generator followed by an integration of the result over the set of generators.

The dependence on Γ^r_{rr} can be eliminated. Adding the variation of a functional of the data (an exact form on $\mathcal{F}$) to the symplectic potential does not affect its curl, the presymplectic 2-form. Thus we are free to subtract from $\Theta_R[\delta]$ the variation

$$\begin{aligned}
&\delta\left[\frac{1}{8\pi G}\int_{S_R}\epsilon\int_{r_0}^{1}[r+r^2\Gamma^r_{rr}]dr\right] \\
&\quad = \quad -\frac{1}{16\pi G}\left\{\int_{S_R}\epsilon\int_{r_0}^{1} -2r^2\delta\Gamma^r_{rr}dr + \int_{S_0}\delta^y\epsilon(1+r_0\Gamma^r_{rr})\right\}.
\end{aligned} \tag{180}$$

To obtain the last equality note firstly that δr_0 is $\delta^y r$ evaluated at S_0 (i.e. $v^- = 1$), and secondly, that $\epsilon_{S_R} r_0 \delta^y r_0 = \frac{1}{2}\bar{\rho}(y)\, dy^1 \wedge dy^2\, \delta^y r_0^2 = \frac{1}{2}\delta^y \epsilon_{S_0}$.[67] We will therefore take as the symplectic potential contributed by $\mathcal{N}_R$

$$\Theta'_R[\delta] = -\frac{1}{16\pi G}\left\{\int_{S_R}\epsilon\int_{r_0}^{1}\frac{1}{2}r^2\partial_r e_{ij}\delta e^{ij}dr + \int_{S_0}\epsilon(\delta^y\lambda + \xi^a_\perp\omega_a)\right\}. \tag{181}$$

Adding the contribution of $\mathcal{N}_L$ we obtain the entire symplectic potential:

$$\begin{aligned}
\Theta'[\delta] = -\frac{1}{16\pi G}\Big\{ &\int_{S_R}\epsilon\int_{r_0}^{1}\frac{1}{2}r^2\partial_r e_{ij}\delta e^{ij}\, dr \\
&+ \int_{S_L}\epsilon\int_{r_0}^{1}\frac{1}{2}r^2\partial_r e_{ij}\delta e^{ij}\, dr \\
&+ \int_{S_0}\epsilon(\delta^{y_R}\lambda + \delta^{y_L}\lambda + \xi^a_{\perp\, R}\omega_a - \xi^a_{\perp\, L}\omega_a)\Big\}.
\end{aligned} \tag{182}$$

All quantities appearing in the integral over $\mathcal{N}_R$ are referred to the a_R coordinates and, similarly, those appearing in the integral over $\mathcal{N}_L$ are referred to the a_L coordinates. In the integral over S_0 the term $\xi^a_{\perp\, L}\omega_a$ appears with a minus sign because under the interchange of L and R, which interchanges n_+ and n_-, the field $\omega_a = [n_+ \cdot \nabla_a n_- - n_- \cdot \nabla_a n_+]/n_- \cdot n_+$ is replaced by $-\omega_a$.

In (182) there appear, aside from the BFC data and their variations, only the two area forms $\epsilon_{S_A} = \bar{\rho}_A dy^1_A \wedge dy^2_A$ and the two vector fields $\xi_{\perp\, A}$. The area forms we know how to express in terms of BFC data (see the end of subsection 4.1), and they will

[67] Strictly speaking the three 2-forms in the equation live in different spaces. But they are equal when they are all pulled back to the cotangent space of $\mathbb{R}^2$ using the y chart.

be left as they are. The vector $\xi_{\perp\, A}$ is the variation of the map s_A that gives the y_A coordinates of a generator as a function of its θ coordinates: $\xi^i_{\perp\, A} = \delta^b y^i_A = \delta s^i_A$ or, transforming to θ components,

$$\xi^a_{\perp\, A} = \frac{\partial \theta^a}{\partial y^i_A} \delta s^i_A. \tag{183}$$

s_A is the inverse of the BFC datum f_A it may be taken as an element of the BFC data, in place of f_A. (Notice that the θ^a are the natural coordinates of s_A.)

It turns out to be helpful to make explicit the dependence of the S_0 integral in (182) on the variations of the s_A:

$$\delta^y \lambda = \delta\lambda - \xi^a_\perp \partial_a \lambda, \tag{184}$$

so

$$\delta^{y_R}\lambda + \delta^{y_L}\lambda + \xi^a_{\perp\, R}\omega_a - \xi^a_{\perp\, L}\omega_a = 2\delta\lambda - \xi^a_{\perp\, R}\omega_{-\, a} - \xi^a_{\perp\, L}\omega_{+\, a}, \tag{185}$$

where $\omega_+ = \omega + d\lambda$ and $\omega_- = -\omega + d\lambda$.[68] With the definitions

$$\hat\omega_{R\, i} = \rho_0 \omega_{-\, a} \frac{\partial \theta^a}{\partial y^i_R} \quad \text{and} \quad \hat\omega_{L\, m} = \rho_0 \omega_{+\, a} \frac{\partial \theta^a}{\partial y^m_L}, \tag{186}$$

the contribution of $\mathcal{N}_R$ to the symplectic potential may be written as

$$\begin{aligned} \Theta'_R[\delta] = -\frac{1}{16\pi G}\Big\{ & \int_{S_R} \epsilon \int_{r_0}^1 \frac{1}{2} r^2 \partial_r e_{ij} \delta e^{ij}\, dr \\ & + \int_{S_0} [\rho_0 \delta\lambda - \hat\omega_{R\, i} \delta s^i_R]\, d\theta^1 \wedge d\theta^2 \Big\}. \end{aligned} \tag{187}$$

and the contribution $\Theta'_L[\delta]$ of $\mathcal{N}_L$ is given by a completely analogous expression.

4.3 Calculation of the presymplectic 2-form in terms of almost free initial data

The first term in (187) is a "bulk" term, an integral over $\mathcal{N}_R$, while the second term, an integral over S_0, is a surface term. There are no contributions from the boundary of $\mathcal{N}_R$ except that from S_0.

The contribution of the hypersurface $\mathcal{N}_R$ to the presymplectic 2-form is $\bar\Omega_R[\delta_1, \delta_2] = \delta_1 \Theta'_R[\delta_2] - (1 \leftrightarrow 2)$. [For convenience the commutator $[\delta_1, \delta_2]$ of the vector fields δ_1 and δ_2 on the space of field configurations $\mathcal{F}$ has been set to zero. As discussed in footnote 31, this may always be done without restricting the action of δ_1 and δ_2 on

[68] These quantities were introduced by Epp in [Epp95].

the fields at the fiducial solution, which is a single point in $\mathcal{F}$.] The bulk term in $\bar{\Omega}_R$ is obtained by varying the bulk term in Θ'_R with r_0 held fixed. It is

$$\frac{1}{16\pi G}\left\{\int_{S_R}\epsilon\int_{r_0}^1\frac{1}{2}r^2\delta_1 e^{ij}\partial_r\delta_2 e_{ij}\,dr-(1\leftrightarrow 2)\right\}. \tag{188}$$

The surface term at S_0 comes both from the surface term in Θ'_R and the variation of r_0 in the bulk term of Θ'_R. The latter contribution is

$$\begin{aligned}&\frac{1}{16\pi G}\left\{\int_{S_R}\epsilon\delta_1^y r_0[\frac{1}{2}r^2\partial_r e_{ij}\delta_2^a e^{ij}]_{r_0}-(1\leftrightarrow 2)\right\}\\ &=\quad\frac{1}{16\pi G}\left\{\int_{S_0}\delta_1^y\epsilon\frac{1}{4}r_0\partial_r e_{ij}\delta_2^a e^{ij}-(1\leftrightarrow 2)\right\}.\end{aligned} \tag{189}$$

(The subscript r_0 on the bracket indicates that the bracketed expression is to be evaluated at $r=r_0$. That is, the integral ranges over S_R with the integrand at each point of S_R given by an expression evaluated at $r=r_0$ on the generator through that point.)

In (189) the derivatives by r along the generators may be replaced by derivatives by $v^-=r/r_0$ using $r_0\partial_r=\partial_{v^-}$, and the variation δ^a may be replaced by δ^y:

$$\delta_1^y r_0\,\delta_2^a e^{ij}-(1\leftrightarrow 2) \tag{190}$$

$$=\delta_1^y r_0\,\delta_2^y e^{ij}-\delta_1^y r_0\,\delta_2^y r_0\partial_r e^{ij}-(1\leftrightarrow 2) \tag{191}$$

$$=\delta_1^y r_0\,\delta_2^y e^{ij}-(1\leftrightarrow 2). \tag{192}$$

The first equality is evidently correct if $\delta_2^y e^{ij}$ is interpreted as the variation, at fixed (v^+,v^-,y^1,y^2), of the a components e^{ij}. The result is stronger than that however. Because the 3-metric on $\mathcal{N}$ is degenerate along the generators it takes the form $h_{ij}dy^i\otimes dy^j$ (see 103). Therefore the metric induced on *any* two dimensional cross section of $\mathcal{N}$ will have y components h_{ij}. The e^{ij} are both the a components of the inverse conformal 2-metric, e^{-1}, on a constant (r,u) surface as well as the components of e^{-1} on a constant (v^+,v^-) surface in the hybrid chart (v^+,v^-,y^1,y^2). As a consequence the $\delta^y e^{ij}$ may also be interpreted as the (v^+,v^-,y^1,y^2) components, or the a components, of $\delta^y e^{-1}$.

The contribution (189) to $\bar{\Omega}_R$ can thus be written as

$$\frac{1}{16\pi G}\left\{\int_{S_0}\delta_1^y\epsilon\frac{1}{4}\partial_{v^-}e_{ij}\delta_2^y e^{ij}-(1\leftrightarrow 2)\right\}. \tag{193}$$

The contribution to $\bar{\Omega}_R$ of the surface term in $\Theta'_R[\delta]$ is

$$-\frac{1}{16\pi G}\left\{\int_{S_0}\delta_1\rho_0\delta_2\lambda-\delta_1\hat{\omega}_{Ri}\delta_2 s_R^i\,d\theta^1\wedge d\theta^2-(1\leftrightarrow 2)\right\}. \tag{194}$$

Summing (188), (193), and (194) one obtains

$$\bar{\Omega}_R[\delta_1,\delta_2] = \frac{1}{16\pi G}\Big\{ \begin{array}{ll} \frac{1}{2} & \int_{S_R} \epsilon \int_{r_0}^{1} r^2 \delta_1 e^{ij} \partial_r \delta_2 e_{ij} dr \\ +\frac{1}{4} & \int_{S_0} \delta_1^y \epsilon \partial_{v^-} e_{ij} \delta_2^y e^{ij} \\ - & \int_{S_0} \delta_1\rho_0\delta_2\lambda - \delta_1\hat{\omega}_{Ri}\delta_2 s_R^i \, d\theta^1 \wedge d\theta^2 - (1 \leftrightarrow 2) \end{array} \Big\}. \quad (195)$$

This is the needed expression for the presymplectic 2-form in terms of the BFC data.

5 The pre-Poisson bracket on initial data

With the expression (195) for the presymplectic 2-form in terms of BFC data in hand we are ready to solve for the auxiliary pre-Poisson bracket satisfying (53):

$$\delta_0\varphi = \bar{\Omega}[\{\varphi,\cdot\}_*,\delta_0] \quad \forall \delta_0 \in L_g^0. \quad (196)$$

Actually, in order to preserve the symmetry between the L and R branches of $\mathcal{N}$, we will solve for an equivalent bracket, $\{\cdot,\cdot\}_\circ$, on a slightly larger "extended" phase space, from which the $*$ brackets between the BFC data may be read off. In subsection 5.2 the resulting bracket is stated explicitly and discussed. The calculation of the bracket is given in subsection (5.3).

Neither the $*$ nor the $\circ$ bracket satisfies the Jacobi relation. (For this reason they are called pre-Poisson brackets and not Poisson brackets.) But recall that (53) and the skew symmetry, linearity and Leibniz rule properties of the $*$ bracket suffice to ensure that the $*$ brackets of observables constructed from the initial data are equal to the Peierls brackets of these and thus satisfy the Jacobi relation.

5.1 Preliminaries

In the following the extended phase space and the $\circ$ bracket will be defined. In addition a useful parametrization of the degrees of freedom encoded in the conformal 2-metric e_{ij} in terms of a single complex valued field, μ, will be presented.

5.1.1 A helpful extension of the phase space

We have introduced the b chart in order to make it easier to treat the two branches of $\mathcal{N}$ democratically - quantities associated with the 2-surface S_0 common to the two branches are referred to the b chart rather than the a chart adapted to either of the branches. However, to be able to solve (53) it is necessary to fix some specific

relation between the coordinates θ^a and the y^i_R and the y^j_L. One could attempt to find a suitably symmetrical relation but this does not seem to be simple. The simplest choice is to equate the θ^a with either the y^i_R or the y^j_L, which would of course break the symmetry between L and R.

A way to maintain the symmetry is to maintain the θ coordinates independent of the y coordinates and use a somewhat different bracket. Maintaining the θ coordinates independent introduces a new gauge degree of freedom, namely the freedom to change the θ chart by a diffeomorphism. The value of the presymplectic 2-form on a given pair of variations

does not depend on the θ chart that has been chosen. Indeed reference to the θ chart can be eliminated altogether by choosing $\theta = y_L$ (for instance) and thus expressing $\bar{\Omega}[\delta_1, \delta_2]$ entirely in terms of the variations of the fields with respect to the a_L and a_R charts. Thus a variation of the BFC data which corresponds solely to a diffeomorphism of the θ coordinates, leaving the relationship between the a_L and a_R coordinates and the fields referred to these invariant, is necessarily mapped to zero by $\bar{\Omega}$. For this reason it is impossible to invert $\bar{\Omega}$ to obtain a bracket on a phase space of initial data including fields referred to the θ chart, unless either the θ^a are taken to be fixed functions of the y^i_R and y^m_L or the phase space is extended by including momenta conjugate to the θ^a.

We shall take essentially the second option, although we will not actually specify variables conjugate to the θ^a. What is really necessary is that suitable functions on the extended phase space generate the θ diffeomorphisms. The original phase space is then recovered as the submanifold on which these generators vanish.

Such an extension can be realized in a quite natural manner. In the expression (195) for the R contribution to the presymplectic 2-form and the corresponding formula for the L contribution the field ω appears in the guise of two distinct quantities, $\hat{\omega}_{R\,i}$ and $\hat{\omega}_{L\,m}$, derived from ω. In the required extended phase space these two are independent fields on S_0. In the original phase space they are of course not independent. They are related by the equation

$$\hat{\omega}_{R\,i}\frac{\partial s^i_R}{\partial \theta^a} + \hat{\omega}_{L\,m}\frac{\partial s^m_L}{\partial \theta^a} = \rho[\omega_{-a} + \omega_{+a}] = 2\rho\frac{\partial}{\partial \theta^a}\lambda, \tag{197}$$

which serves as a constraint that defines the original phase space of initial data as a submanifold of the extended phase space. As we shall see shortly this constraint also generates diffeomorphisms of the θ chart.

The symplectic potential on the extended phase space, denoted $\hat{\Theta}$, is taken to be equal to the expression (187) for Θ' but with $\hat{\omega}_{R\,i}$ and $\hat{\omega}_{L\,j}$ independent fields. The presymplectic 2-form $\hat{\Omega}$ is the curl of $\hat{\Theta}$. Explicitly $\hat{\Omega}$ is the sum of a contribution

from $\mathcal{N}_R$, $\hat{\Omega}_R = A_R + B_R + C_R$ with

$$A_R[\delta_1, \delta_2] = -\frac{1}{16\pi G}\int_{S_0} \delta_1\rho_0\delta_2\lambda - \delta_1\hat{\omega}_{R\,i}\delta_2 s^i_R \, d\theta^1 \wedge d\theta^2 - (1 \leftrightarrow 2) \quad (198)$$

$$B_R[\delta_1, \delta_2] = \frac{1}{64\pi G}\int_{S_0} \delta^y_1\epsilon\partial_{v^-}e_{ij}\delta^y_2 e^{ij} - (1 \leftrightarrow 2) \quad (199)$$

$$C_R[\delta_1, \delta_2] = \frac{1}{32\pi G}\int_{S_R} \epsilon\int_{r_0}^1 r^2\delta_1 e^{ij}\partial_r\delta_2 e_{ij}dr - (1 \leftrightarrow 2), \quad (200)$$

and an entirely analogous contribution $\hat{\Omega}_L$ from $\mathcal{N}_L$ (obtained by substituting L for R, and v^+ for v^-, in $\hat{\Omega}_R$).

The auxiliary bracket on the extended phase space, $\{\cdot,\cdot\}_\circ$, is defined by the requirement that

$$\delta\varphi = \hat{\Omega}[\{\varphi,\cdot\}_\circ, \delta] \quad (201)$$

for all extended phase space initial data φ on the interior of $\mathcal{N}$ and all variations δ of the data compatible with the metric consistency constraint (109), and the condition that $\delta e_{ij} = 0$ at the two ends S_R and S_L of $\mathcal{N}$. These variations δ will be termed "admissible".

Note that we have weakened the condition on the variation δe_{ij} of the a chart components of e. We are not requiring it to vanish in a neighbourhood of $\partial\mathcal{N}$, only on $\partial\mathcal{N}$ itself. This does not lead to any actual change of the implications of (201) for the specific $\hat{\Omega}$ we are using. Restricting the admissible δ to ones for which δe_{ij} vanishes in some neighbourhood of $\partial\mathcal{N}$ does not enlarge the set of brackets solving (201), as the reader may easily verify when this condition is solved for $\{\cdot,\cdot\}_\circ$ in subsection 5.3. But a simpler definition of the admissible δ seems preferable, and may facilitate understanding of the results, especially in connection with the Jacobi relations. In any case it is clear that enlarging the class of admissible δ does not weaken (201), and so our key result, that the brackets satisfying this relation reproduce the Peierls brackets of observables (when the constraint (197) is imposed) continues to hold.

Let us return to the constraint (197). Imposing this constraint on the interior of S_0 is equivalent to requiring that

$$\kappa[v] = \frac{1}{16\pi G}\int_{S_0} v^a[2\rho\partial_a\lambda - \hat{\omega}_{R\,i}\partial_a s^i_R - \hat{\omega}_{L\,m}\partial_a s^m_L]d\theta^1 \wedge d\theta^2 \quad (202)$$

$$= -\hat{\Theta}[\pounds_v], \quad (203)$$

vanishes for all smooth vector fields v tangent to S_0 and vanishing on ∂S_0. $\kappa[v]$ acts as a diffeomorphism generator, it produces a variation $\delta^y\theta^a = -v^a$ in the θ coordinates at fixed y_R and y_L, and no change in the relation between the a_R and a_L charts or in the fields as functions of either of those charts. Equivalently it acts as $\pounds_v$ on the fields as functions of the θ^a.

To see this note that

$$\hat{\Omega}[\pounds_v, \delta] = \pounds_v \hat{\Theta}[\delta] - \delta \hat{\Theta}[\pounds_v], \tag{204}$$

where δv has been set to zero, so that $[\delta, \pounds_v] = \pounds_{\delta v} = 0$. $\pounds_v$ acts only on the S_0 surface term in $\hat{\Theta}[\delta]$ since the bulk term, in which no fields referred to the θ^a intervene, is invariant under diffeomorphisms of the θ chart. But since the integrand of the S_0 term is a scalar density under diffeomorphisms of the θ and v vanishes on ∂S_0 the S_0 contribution to $\hat{\Theta}[\delta]$ is also invariant under the diffeomorphisms generated by v. Thus $\pounds_v \hat{\Theta}[\delta] = 0$ and

$$\delta\kappa[v] = \hat{\Omega}[\pounds_v, \delta]. \tag{205}$$

Note that δ need not be an admissible variation. Admissibility is not assumed in (204) nor in obtaining the explicit expression (198 - 200) for $\hat{\Omega}$ from $\hat{\Theta}$, via the calculation of subsection 4.3. (Indeed, in 4.3 the variations are only assumed to satisfy the conditions a) and b) of subsection 4.1.) We may therefore take δ to be the action $\{\varphi, \cdot\}_\circ$ of an initial datum φ, in which case

$$\{\kappa[v], \varphi\}_\circ \equiv -\delta\kappa[v] = \hat{\Omega}[\{\varphi, \cdot\}_\circ, \pounds_v]. \tag{206}$$

Since $\pounds_v$ is an admissible variation (in fact, it leaves e_{ij} invariant) equation (201) implies that

$$\{\kappa[v], \varphi\}_\circ = \pounds_v \varphi. \tag{207}$$

Here $\pounds_v$ acts only on the θ dependence of the fields. That is, it is equivalent to a generator of diffeomorphisms of the θ coordinates.

Because it preserves the symmetry between the branches of $\mathcal{N}$ the bracket $\{\cdot, \cdot\}_\circ$ rather than $\{\cdot, \cdot\}_*$ will be given explicitly here. Note however that the bracket $\{\cdot, \cdot\}_*$ on the original phase space corresponding to the choice $\theta^1 = y^1_L$, $\theta^2 = y^2_L$ (i.e. $s_L = \mathrm{id}$) can be recovered easily from $\{\cdot, \cdot\}_\circ$ as a Dirac bracket:

$$\{\cdot, \cdot\}_* = \{\cdot, \cdot\}_\circ - \int_{S_0} \frac{\partial \theta^a}{\partial y^l_L} \left[\{\cdot, s^l_L\}_\circ \{\kappa_a, \cdot\}_\circ - \{\cdot, \kappa_a\}_\circ \{s^l_L, \cdot\}_\circ\right] \, d\theta^1 \wedge d\theta^2, \tag{208}$$

where $\kappa_a \equiv \kappa[\partial_a] = \frac{1}{16\pi G}[2\rho\partial_a\lambda - \hat{\omega}_{Ri}\partial_a s^i_R - \hat{\omega}_{Lm}\partial_a s^m_L]$, and $\frac{\partial\theta^a}{\partial y^l_L}$, with the fixing of θ adopted is a Kronecker delta. Of course the $*$ bracket may also be obtained by solving the original equation (53) with this fixing of the θ chart.

The explicit form of the $\circ$ brackets, given in subsection 5.2, shows that the only datum that has non-zero $\circ$ bracket with s_L is $\hat{\omega}_L$ (see (241) and the subsequent discussion). $\{\cdot, \cdot\}_*$ thus differs from $\{\cdot, \cdot\}_\circ$ only when one of the arguments is $\hat{\omega}_L$. This datum is not independent on the constraint manifold so the $*$ brackets of a complete set of phase space coordinates on the gauge fixed constraint manifold, namely the data

we have been considering excluding s_L and $\hat{\omega}_L$, are identical to the corresponding $\circ$ brackets. The $*$ brackets involving $\hat{\omega}_L$ can be obtained from brackets between these other data by substituting the expression for $\hat{\omega}_L$ in terms of these provided by the constraint (197) and the gauge condition $s_L = \mathrm{id}$. The $*$ brackets of s_L of course vanish.

5.1.2 A useful parametrization of the conformal 2-metric degrees of freedom

We turn now to the definition of a useful parametrization of the conformal 2-metric e. The unimodular symmetric matrix field e_{ab} is free initial data in the sense that it is unrestricted by the field equations, but of course the components of e are algebraically restricted by the requirements of symmetry and unimodularity. It is thus convenient to parametrize the two degrees of freedom of e by an unconstrained complex number. We shall do this as follows: The degenerate line element on $\mathcal{N}$ can always be expressed in terms the complex coordinate $z = \theta^1 + i\theta^2$ as

$$ds^2 = h_{ab}d\theta^a d\theta^b = \rho(1 - |\mu|^2)^{-1}[dz + \mu d\bar{z}][d\bar{z} + \bar{\mu}dz]. \tag{209}$$

with μ a complex number valued field of modulus less than 1. μ provides the desired parametrization of e. In component form (with respect to the θ coordinate basis)

$$e_{ab} = \frac{1}{1 - |\mu|^2}\begin{bmatrix} |1+\mu|^2 & 2\mathrm{Im}\mu \\ 2\mathrm{Im}\mu & |1-\mu|^2 \end{bmatrix}. \tag{210}$$

Under a transformation of coordinates $\theta \to \theta'$ in which the θ' coordinates, like the θ coordinates, are constant on the generators of $\mathcal{N}$, the components e_{ab} are transformed to

$$e'_{cd} = \frac{\partial\theta^a}{\partial\theta'^c}\frac{\partial\theta^b}{\partial\theta'^d}|det\frac{\partial\theta'}{\partial\theta}|e_{ab} \tag{211}$$

(a fact that was used in the definition of the constraint (109)). The corresponding transformation of μ is

$$\mu \to \mu' = [\frac{\partial z}{\partial\bar{z}'} + \mu\frac{\partial\bar{z}}{\partial\bar{z}'}]/[\frac{\partial z}{\partial z'} + \mu\frac{\partial\bar{z}}{\partial z'}]. \tag{212}$$

The μ field referred to the y_R chart will be denoted by μ_R and that referred to the y_L chart by μ_L.

5.2 The brackets

In this subsection the $\circ$ brackets will be given between the data $\hat{\omega}_{Ri}$, $\hat{\omega}_{Lm}$, s_R^j, s_L^n, λ, ρ_0, and μ and $\bar{\mu}$ (or equivalently e_{ab}), where the conformal 2-metric data μ and

$\bar{\mu}$ are, like the other data, *referred to the b chart*. A subset of these form a *free and complete* data set. Moreover, the $\circ$ brackets among the data in this subset are equal to their $*$ brackets.

As pointed out earlier, the constraint (109) that the a_R and a_L components of e must satisfy at S_0 is equivalent to the requirement that e_{ab} at S_0 obtained by transforming $e_{R\,ij}$ from the a_R chart to the b chart is the same as obtained by transforming $e_{L\,mn}$ from the a_L chart, i.e. it is equivalent to requiring that e_{ab} can be consistently defined. The constraint (109) thus disappears if the b components, e_{ab}, are used to specify the conformal 2-metric throughout $\mathcal{N}$, in place of $e_{R\,ij}$ on $\mathcal{N}_R$ and $e_{L\,mn}$ on $\mathcal{N}_L$.

The other constraint, (197), is still present, and so is, necessarily, a gauge fixing condition defining the θ coordinates. However, as shown in subsection 5.1.1, if the simple gauge fixing $s_L = \mathrm{id}$ is adopted then (197) can always be solved for $\hat{\omega}_L$, and the remaining data e_{ab}, $\hat{\omega}_{R\,i}$, s^j_R, λ, and ρ_0 form a free and complete set. Using of the explicit expressions for the $\circ$ brackets given here it is easy to check that the $*$ (208) coincides with the $\circ$ bracket between these data. To maintain the symmetry between L and R in the formalism, and in order to not commit ourselves to any specific gauge for the θ coordinates, the $\circ$ brackets between all the data, including $\hat{\omega}_L$ and s_L will be given.

For 1 and 2 points on S_0 (or more precisely values of the b coordinates corresponding to points on S_0)

$$\{\lambda(1), \rho_0(2)\}_\circ = -8\pi G\delta^2(\theta(2) - \theta(1)), \tag{213}$$

$$\{\hat{\omega}_{R\,i}(1), s^j_R(2)\}_\circ = -16\pi G\delta^j_i\delta^2(\theta(2) - \theta(1)), \tag{214}$$

$$\{\hat{\omega}_R[f], \lambda(1)\}_\circ = \pi G[(\partial_{v^-}e^{ab} - \partial_{v^+}e^{ab})\pounds_f e_{ab}]_1 \tag{215}$$

$$\{\hat{\omega}_R[f_1], \hat{\omega}_R[f_2]\}_\circ = -2\pi G\int_{S_0} \pounds_{f_1} e_{ab}\,\partial_{v^-}e^{ab}\pounds_{f_2}\epsilon - (1 \leftrightarrow 2) \tag{216}$$

$$\{\hat{\omega}_R[f], \hat{\omega}_L[g]\}_\circ = 2\pi G\int_{S_0} [\pounds_f e_{ab}\partial_{v^+}e^{ab}\pounds_g\epsilon - \pounds_g e_{ab}\partial_{v^-}e^{ab}\pounds_f\epsilon], \tag{217}$$

where $\hat{\omega}_R[f] = \int_{S_0}\hat{\omega}_{R\,i}f^i d\theta^1 \wedge d\theta^2$ with f a test vector field tangent to S_0, and $\hat{\omega}_L[g]$ and g are defined similarly. Note that *the y_R components f^i* of f, and similarly the y_L components g^m of g, are taken to be independent of the dynamical fields and thus $\circ$ commute with everything. This is important to remember in order to interpret the given expressions for the brackets correctly, as can be clearly seen when the smearing fields are eliminated.

Expressions analogous to (214), (215), and (216) give the brackets $\{\hat{\omega}_{L\,m}(1), s^n_L(2)\}_\circ$, $\{\lambda(1), \hat{\omega}_L[g]\}_\circ$, and $\{\hat{\omega}_L[g_1], \hat{\omega}_L[g_2]\}_\circ$ respectively.

For 1 and 2 points on the same branch of $\mathcal{N}$

$$\{\mu(1), \bar{\mu}(2)\}_\circ = 2\pi G\,\delta^2(\theta(2) - \theta(1))\,sgn(1,2)$$

$$[\frac{1-|\mu|^2}{\sqrt{\rho}}]_1[\frac{1-|\mu|^2}{\sqrt{\rho}}]_2\, e^{\int_1^2 \frac{1}{1-|\mu|^2}[\bar{\mu}d\mu-\mu d\bar{\mu}]}, \tag{218}$$

where for 1 and 2 lying on the same generator (i.e. $\theta(1)=\theta(2)$)

$$sgn(1,2)=\begin{cases} +1 & \text{if 2 is further from } S_0 \text{ along the generator than 1} \\ -1 & \text{if 2 is closer to } S_0 \text{ along the generator than 1} \end{cases} \tag{219}$$

and the integral in the exponential is evaluated along the segment of the generator from 1 to 2. Note that this defines the bracket between μ and $\bar{\mu}$ smeared with smooth test functions on $\mathcal{N}$.

When 1 and 2 both lie on S_0 $\{\mu(1),\bar{\mu}(2)\}_\circ=0$. This is not unambiguously implicit in (218). It is an additional specification of the bracket compatible with the defining equation (201).

For 1 and 2 any two points in $int\mathcal{N}$

$$0=\{\mu(1),\mu(2)\}_\circ=\{\bar{\mu}(1),\bar{\mu}(2)\}_\circ, \tag{220}$$

Notice that when 1 and 2 both lie on S_0 (220), together with the vanishing of $\{\mu(1),\bar{\mu}(2)\}_\circ$ in this case, implies that $\{e^{cd}(1),e_{ab}(2)\}_\circ=0$.

These brackets are not uniquely determined by (201). In particular $\delta^2(\theta(2)-\theta(1))\,sgn(1,2)$ in (218) may be replaced by $\delta^2(\theta(2)-\theta(1))\,sgn(1,2)+i\Upsilon(\theta(1),\theta(2))$, where Υ is a real distribution on θ, and possibly a function of the data, resembling $\delta^2(\theta(2)-\theta(1))$ in that it has support only at $\theta(2)=\theta(1)$ and that it transforms like $\delta^2(\theta(2)-\theta(1))$ under diffeomorphisms of the θ chart.

This indeterminacy arises for the following reason: Denote the a chart μ and $\bar{\mu}$ fields on the truncating surface $S_A\subset\partial\mathcal{N}$ of a given branch by $\dot{\mu}$ and $\dot{\bar{\mu}}$. The bracket is only defined on data on the *interior* of $\mathcal{N}$, but we may define $\{\dot{\mu}(y),\cdot\}_\circ$ and $\{\dot{\bar{\mu}}(y),\cdot\}_\circ$ to be the limits of $\{\mu(p),\cdot\}_\circ$ and $\{\bar{\mu}(p),\cdot\}_\circ$, respectively, as p tends to S_A along the generator specified by y. For any admissible variation δ (which we always take to be smooth)

$$\hat{\Omega}[\{\dot{\mu}(y),\cdot\}_\circ,\delta]=\lim_{p\to S_A}\hat{\Omega}[\{\mu(p),\cdot\}_\circ,\delta]=\lim_{p\to S_A}\delta\mu(p)=0, \tag{221}$$

and similarly for $\{\dot{\bar{\mu}}(y),\cdot\}_\circ$. (201) thus permits

the addition of multiples of $\{\dot{\mu}(y),\cdot\}_\circ$ and $\{\dot{\bar{\mu}}(y),\cdot\}_\circ$ to any solution $\{\varphi_I,\cdot\}_\circ$. This freedom in the brackets is greatly reduced by the requirements of causality and anti-symmetry, but not entirely eliminated.

Another possible indeterminacy is associated with the bracket $\{e^{cd}(1),e_{ab}(2)\}_\circ$ for $1,2\in S_0$. The vanishing of this bracket is shown to be consistent with (201), but it is not shown to be necessary. On the other hand, no candidate for an alternative solution for $\{e^{cd}(1),e_{ab}(2)\}_\circ$ was found. In other words, this bracket has not been demonstrated to be uniquely determined, but it may be so.

The freedom in the bracket $\{\mu(1), \bar{\mu}(2)\}_\circ$ propagates to some other brackets. However, if it is assumed that $\{\mu(1), \bar{\mu}(2)\}_\circ$ is given by the expression (218) and $\{e^{cd}(1), e_{ab}(2)\}_\circ = 0$ for $1, 2 \in S_0$ all other brackets are uniquely determined by (201). Here I will make this choice, as it is the simplest and provides the most natural seeming solution to (201).

For $1 \in S_0$ and $2 \in \mathcal{N}_R - S_0$

$$\{\lambda(1), e_{ab}(2)\}_\circ = \frac{1}{4}[\partial_{v^+} e_{cd}]_1 \{e^{cd}(1), e_{ab}(2)\}_\circ - 4\pi G[\frac{v^-}{\rho_0}\partial_{v^-} e_{ab}]_2 \delta^2(\theta(2) - \theta(1)), \tag{222}$$

$$\begin{aligned}\{\hat{\omega}_R[f], e_{ab}(2)\}_\circ &= -\frac{1}{2}\int_{S_0} \epsilon\, \pounds_f e_{cd} \{e^{cd}, e_{ab}(2)\}_\circ \\ &\quad -16\pi G[\pounds_f e_{ab} - \frac{1}{2}\partial_{v^-} e_{ab}\frac{\pounds_f \rho_0}{\rho_0}]_2,\end{aligned} \tag{223}$$

$$\{\hat{\omega}_L[g], e_{ab}(2)\}_\circ = \frac{1}{2}\int_{S_0} [\epsilon\, \pounds_g e_{cd} - \pounds_g \epsilon\, \partial_{v^+} e_{cd}]\{e^{cd}, e_{ab}(2)\}_\circ. \tag{224}$$

Of course analogous expressions with the roles of $\mathcal{N}_R$ and $\mathcal{N}_L$ reversed give the corresponding brackets when $2 \in \mathcal{N}_L - S_0$.

When 2 lies on S_0

$$\{\lambda(1), e_{ab}(2)\}_\circ = -2\pi G\frac{1}{\rho_0}[\partial_{v^-} e_{ab} + \partial_{v^+} e_{ab}]\delta^2(\theta(2) - \theta(1)), \tag{225}$$

$$\{\hat{\omega}_R[f], e_{ab}(2)\}_\circ = -8\pi G[\pounds_f e_{ab} - \frac{1}{2}\partial_{v^-} e_{ab}\frac{\pounds_f \rho_0}{\rho_0}]_2. \tag{226}$$

$$\{\hat{\omega}_L[g], e_{ab}(2)\}_\circ = -8\pi G[\pounds_g e_{ab} - \frac{1}{2}\partial_{v^+} e_{ab}\frac{\pounds_g \rho_0}{\rho_0}]_2. \tag{227}$$

These brackets for $2 \in S_0$ are the averages of the expressions for the same brackets valid in the cases $2 \in \mathcal{N}_R - S_0$ and $2 \in \mathcal{N}_L - S_0$. (Recall that $\{e^{cd}(1), e_{ab}(2)\}_\circ = 0$ when both 1 and 2 lie on S_0.)

All other brackets vanish. In particular

$$0 = \{\lambda(1), \lambda(2)\}_\circ. \tag{228}$$

and s_R, s_L and ρ_0 commute (that is, they have vanishing $\circ$ brackets) with everything except $\hat{\omega}_R$, $\hat{\omega}_L$, and λ respectively.

The requirement that κ generates diffeomorphisms of the θ chart - specifically that $\{\kappa[v], \varphi\}_\circ = -\pounds_v \varphi$ for all data φ on $int\mathcal{N}$ - provides a non-trivial check of the brackets. The reader may easily verify that the expressions for the brackets given here satisfy this requirement.

Notice that by (218) and (220) the variation $\{\mu(1),\cdot\}_\circ$ does not preserve the reality of the metric. This corresponds to the fact that μ is complex. The action of a real functional of μ and $\bar\mu$ does preserve the reality of the metric, as can be seen easily from the relations

$$\overline{\{\mu(1),\bar\mu(2)\}_\circ} = \{\bar\mu(1),\mu(2)\}_\circ, \tag{229}$$
$$\overline{\{\mu(1),\mu(2)\}_\circ} = \{\bar\mu(1),\bar\mu(2)\}_\circ, \tag{230}$$

which follow from (218) and (220). (229) and

(229) can be interpreted as asserting that the bracket in itself, $\{\cdot,\cdot\}_\circ$, is real, so that complex conjugation acts only on it's arguments.

Since the coordinate systems y_R, y_L, and θ labelling the generators of $\mathcal{N}$ are essentially arbitrary it is important to verify that the brackets are invariant under diffeomorphisms of these coordinates. All the data except μ and $\bar\mu$ transform as tensor or tensor density fields under such transformations. For all the brackets except those involving μ and $\bar\mu$ it is therefore easy to check that the brackets and the expressions proposed for them transform in the same way under the various possible coordinate transformations. Moreover, the transformation law (212) of μ shows immediately that $\{\mu(1),\mu(2)\}_\circ = 0$ is a coordinate invariant statement. The only non-trivial case is therefore the bracket (218).

To verify the invariance under coordinate transformations of the equation (218) note first that $\delta^2(\theta(2)-\theta(1))\,sgn(1,2)\frac{1}{\sqrt{\rho_1}}\frac{1}{\sqrt{\rho_2}}$ is invariant. From (212) one shows that a change of coordinates transforms the ratio of a variation $\Delta\mu$ and $1-|\mu|^2$ by a phase factor:

$$\frac{\Delta\mu'}{1-|\mu'|^2} = \frac{\overline{\alpha+\mu\beta}}{\alpha+\mu\beta}\frac{\Delta\mu}{1-|\mu|^2}, \tag{231}$$

where $\alpha = \frac{\partial z}{\partial z'}$ and $\beta = \frac{\partial \bar z}{\partial z'}$. Thus

$$[\frac{1}{1-|\mu'|^2}]_1\{\mu'(1),\bar\mu'(2)\}_\circ[\frac{1}{1-|\mu'|^2}]_2 =$$
$$[\frac{\overline{\alpha+\mu\beta}}{\alpha+\mu\beta}]_1[\frac{\alpha+\mu\beta}{\overline{\alpha+\mu\beta}}]_2[\frac{1}{1-|\mu|^2}]_1\{\mu(1),\bar\mu(2)\}_\circ[\frac{1}{1-|\mu|^2}]_2. \tag{232}$$

To complete the demonstration of the invariance of (218) we only have to show that the phase $\exp(\int_1^2 \frac{1}{1-|\mu|^2}[\bar\mu d\mu - \mu d\bar\mu])$ transforms in the same way.

(231) and (212) show that

$$\frac{\bar\mu' d\mu'}{1-|\mu'|^2} = \frac{\beta+\bar\mu\alpha}{\alpha+\mu\beta}\frac{d\mu}{1-|\mu|^2} \tag{233}$$
$$= \frac{\beta d\mu}{\alpha+\mu\beta} + \frac{\bar\mu d\mu}{1-|\mu|^2} \tag{234}$$

$$= \quad d\log(\alpha+\mu\beta) + \frac{\bar{\mu}d\mu}{1-|\mu|^2}. \tag{235}$$

It follows that indeed

$$e^{\int_1^2 \frac{1}{1-|\mu'|^2}[\bar{\mu}'d\mu'-\mu'd\bar{\mu}']} = [\frac{\overline{\alpha+\mu\beta}}{\alpha+\mu\beta}]_1[\frac{\alpha+\mu\beta}{\overline{\alpha+\mu\beta}}]_2\, e^{\int_1^2 \frac{1}{1-|\mu|^2}[\bar{\mu}d\mu-\mu d\bar{\mu}]}. \tag{236}$$

The equation (218) is therefore invariant under transformations of the θ chart.

(218) has a further invariance. It is invariant under reparametrization of the generators. In fact (218) does not even refer to a particular parametrization of the generators. This makes it easy to take the flat spacetime limit of this bracket, and it suggests the conjecture that $\{\mu,\bar{\mu}\}_\circ$ is given by the expression (218) even when the area distance is not a good parameter along the generators. For instance, in flat spacetime with $\mathcal{N}$ swept out by parallel generators (neither diverging nor converging), or in a generic spacetime along a generator with neighbours which initially diverge and then re converge. Checking this conjecture is left to future work.

Invariance of the expressions for the brackets under transformations of the θ coordinates is necessary because these coordinates are arbitrary, but this is not so for the parametrization of the generators, because $v = r/r_0$ is not arbitrary. It is completely determined by the geometry of $\mathcal{N}$. Indeed the expressions for several of the brackets, involving $\partial_{v^-}e$ and $\partial_{v^+}e$ at S_0, are not invariant under such reparametrizations of the generators. Of course one may still re express these brackets in terms of another parametrization, λ, of the generators by replacing $\partial_v e_{ab}$ at S_0 by

$$\frac{\partial\lambda}{\partial v}\partial_\lambda e_{ab} = 2\frac{\rho_0}{\partial_\lambda\rho}\partial_\lambda e_{ab} \tag{237}$$

One sees that the brackets cannot all be straightforwardly extended to hypersurfaces $\mathcal{N}$ with vanishing expansion of the generators at S_0. The area distance is not a good parameter at S_0 in this case, and when it is replaced by a good parameter, such as an affine parameter, several of the brackets become undefined. The comparison of the present theory with canonical formulations of general relativity linearized about Minkowski space [AG73] in terms of data on null hyperplanes is thus a delicate matter which is also left to future investigations.

5.3 Calculation of the brackets

How were these brackets obtained from (201)? In the following (201) will be solved step by step, yielding the brackets given above and at the same time demonstrating that $\{\cdot,\cdot\}_\circ$ defined by these brackets really satisfies (201).

We begin by considering (201) for variations δ such that $0 = \delta e = \delta s_L = \delta s_R = \delta\rho_0$. Then

$$\hat{\Omega}[\{\varphi(1),\cdot\}_\circ,\delta] = A[\{\varphi(1),\cdot\}_\circ,\delta] = \\ -\frac{1}{16\pi G}\int_{S_0} 2\{\varphi(1),\rho_0\}_\circ\delta\lambda + \{\varphi(1),s^i_R\}_\circ\delta\hat{\omega}_{Ri} + \{\varphi(1),s^m_L\}_\circ\delta\hat{\omega}_{L\,m}\, d\theta^1\wedge d\theta^2 \quad (238)$$

Substituting for φ each of the fields coordinatizing the extended phase space one finds that the only non-zero bracket involving ρ_0 is (213),

$$\{\lambda(1),\rho_0(2)\}_\circ = -8\pi G\delta^2(\theta(2)-\theta(1)), \quad (239)$$

the only non-zero bracket with s_R is (214),

$$\{\hat{\omega}_{Ri}(1),s^j_R(2)\}_\circ = -16\pi G\delta^j_i\delta^2(\theta(2)-\theta(1)), \quad (240)$$

and the only non-zero bracket with s_L is

$$\{\hat{\omega}_{L\,m}(1),s^n_L(2)\}_\circ = -16\pi G\delta^n_m\delta^2(\theta(2)-\theta(1)). \quad (241)$$

Moreover, it is easy to see that, given these non-zero brackets and the fact that all other brackets involving ρ_0, s_R, and s_L vanish, (201) is satisfied for $\varphi = \rho_0$, s^i_R or s^m_L and *all* δ.

Now let us consider (201) with $\varphi = \mu_R$ evaluated at fixed values of the a_R coordinates corresponding to a point $1 \in \mathcal{N}_R - S_0$, and admissible variations δ such that $0 = \delta s_L = \delta s_R = \delta\rho_0$ but δe not necessarily zero (except of course on $\partial\mathcal{N}$). This will give us the $\circ$ brackets of μ with μ and $\bar{\mu}$.[69]

To solve this condition we first express $\hat{\Omega}[\{\mu(1),\cdot\}_\circ,\delta]$ in terms of μ, $\bar{\mu}$, and their variations. Since we are only considering variations δ that satisfy $0 = \delta s_R = \delta\rho_0$ and since $0 = \{\mu, s^i_R\}_\circ = \{\mu,\rho_0\}_\circ$

$$\hat{\Omega}_R[\{\mu(1),\cdot\}_\circ,\delta] = C_R[\{\mu(1),\cdot\}_\circ,\delta] = \frac{1}{32\pi G}\int_{S_R}\epsilon\int_{r_0}^1 r^2\delta_1 e^{ij}\partial_r\delta_2 e_{ij}dr - (1\leftrightarrow 2), \quad (242)$$

with $\delta_1 = \{\mu(1),\cdot\}_\circ$ and $\delta_2 = \delta$. To this we must add an entirely analogous expression contributed by $\mathcal{N}_L$.

[69] To lighten the notation the subscripts R and L indicating the branch to which variables are referred will be dropped when the context makes this information redundant. In particular μ will be used to denote variously μ_R, μ_L, μ referred to the θ chart, or several of these indistinctly, as the context indicates. For example, in the following paragraphs (until equation (263)), concerned with the brackets of $\mu_R(1)$ for $1 \in \mathcal{N}_R - S_0$, $\mu(1)$ will denote $\mu_R(1)$ and plain μ denotes μ_R, μ_L, or either depending on the context.

[Note that while δ_2 is smooth, admissible, and real in the sense that $\delta_2\bar{\mu}$ is the complex conjugate of $\delta_2\mu$, $\delta_1 = \{\mu(1), \cdot\}_\circ$ need not have any of these properties (and indeed, it turns out to have none of them). In particular we shall see that $\delta_1\bar{\mu}$ is *not* the complex conjugate of $\delta_1\mu$, so this variation takes us outside the space of real metric fields. All the same there is no ambiguity in the definition of $\delta_1 e_{ij}$. Even for real variations, such as δ, $\delta\mu$ and $\delta\bar{\mu}$ are *linearly* independent, that is, no non-zero pair of constants a, b exist such that at a given point $a\delta\mu + b\delta\bar{\mu} = 0$ for all possible real δ. e_{ij} thus has uniquely defined partial derivatives by μ and $\bar{\mu}$, which in turn define $\delta_1 e_{ij}$ unambiguously, even when $\delta_1\bar{\mu} \neq \overline{\delta_1\mu}$.]

In terms of μ

$$\begin{aligned}
&\delta_1 e^{ij}\partial_r\delta_2 e_{ij} - (1 \leftrightarrow 2) \\
&\quad = \quad -4\frac{1}{(1-|\mu|^2)^2}\{\delta_1\mu\partial_r\delta_2\bar{\mu} + \delta_1\bar{\mu}\partial_r\delta_2\mu\} \\
&\qquad -8\frac{1}{(1-|\mu|^2)^3}[\mu\partial_r\bar{\mu} - \bar{\mu}\partial_r\mu]\delta_1\mu\delta_2\bar{\mu} - (1 \leftrightarrow 2).
\end{aligned} \tag{243}$$

[This can be obtained as follows: By a direct calculation from (210) one sees that

$$\Delta e_{ij}\Delta e^{ij} = -8\frac{1}{(1-|\mu|^2)^2}\Delta\mu\Delta\bar{\mu}, \tag{244}$$

for any variation Δ. (This is valid even when $\Delta\bar{\mu}$ is not the complex conjugate of $\Delta\mu$.) Now, substituting $\Delta_1 + \Delta_2$ for Δ in (244) and taking the part linear in Δ_1 one obtains

$$\Delta_1 e_{ij}\Delta_2 e^{ij} = -4\frac{1}{(1-|\mu|^2)^2}\{\Delta_1\mu\Delta_2\bar{\mu} + \Delta_1\bar{\mu}\Delta_2\mu\}. \tag{245}$$

In particular, with $\Delta_1 = \partial_r$ and $\Delta_2 = \delta_1$

$$\partial_r e_{ij}\delta_1 e^{ij} = -4\frac{1}{(1-|\mu|^2)^2}\{\partial_r\mu\delta_1\bar{\mu} + \partial_r\bar{\mu}\delta_1\mu\}. \tag{246}$$

Finally, by acting with δ_2 on (246) and anti-symmetrizing with respect to interchange of δ_1 and δ_2 one obtains (243).]

If we let

$$\alpha(r, y) = \int_{r_0}^{r} \frac{1}{1-|\mu|^2}[\bar{\mu}\partial_r\mu - \mu\partial_r\bar{\mu}]\ dr, \tag{247}$$

where the integral is taken at constant y^i, that is, along a generator of $\mathcal{N}$, then

$$\begin{aligned}
&\delta_1 e^{ij}\partial_r\delta_2 e_{ij} - (1 \leftrightarrow 2) \\
&\quad = \quad -4\{\frac{e^{\alpha}\delta_1\mu}{1-|\mu|^2}\partial_r[\frac{e^{-\alpha}\delta_2\bar{\mu}}{1-|\mu|^2}] + \frac{e^{-\alpha}\delta_1\bar{\mu}}{1-|\mu|^2}\partial_r[\frac{e^{\alpha}\delta_2\mu}{1-|\mu|^2}]\} - (1 \leftrightarrow 2).
\end{aligned} \tag{248}$$

(Note that α is pure imaginary, so e^α is a phase).

This invites us to define, for any variation Δ,

$$\Box = \frac{\sqrt{\rho_y}e^{\alpha}}{1-|\mu|^2}\Delta\mu \qquad \overline{\Box} = \frac{\sqrt{\rho_y}e^{-\alpha}}{1-|\mu|^2}\Delta\bar{\mu}. \tag{249}$$

$\overline{\Box}$ is a *formal* complex conjugate of $\Box$, obtained from $\Box$ via the substitutions $\mu \leftrightarrow \bar{\mu}$ and $\Delta\mu \leftrightarrow \Delta\bar{\mu}$. When Δ is a real variation, so that $\Delta\bar{\mu} = \overline{\Delta\mu}$, $\overline{\Box}$ really is the complex conjugate of $\Box$, but for variations, such as δ_1, which are not real this is not the case.

With these definitions

$$\begin{aligned} C[\{\mu(1),\cdot\}_\circ,\delta] = -\frac{1}{8\pi G}[& \int_{S_R} dy^1_R \wedge dy^2_R \int_{r_{R\,0}}^1 \Box_{R\,1}\partial_r\overline{\Box}_{R\,2} + \overline{\Box}_{R\,1}\partial_r\Box_{R\,2}dr \\ & + \int_{S_L} dy^1_L \wedge dy^2_L \int_{r_{L\,0}}^1 \Box_{L\,1}\partial_r\overline{\Box}_{L\,2} + \overline{\Box}_{L\,1}\partial_r\Box_{L\,2}dr \\ & - (1 \leftrightarrow 2)]. \end{aligned} \tag{250}$$

($\Box_L$ and $\Box_R$ signify $\Box$ formed according to (249) from fields on $\mathcal{N}_L$, referred to the a_L chart, and fields on $\mathcal{N}_R$, referred to the a_R chart, respectively.)

The contribution of either branch to (250) may be integrated by parts in two different ways:

$$\begin{aligned} \int_{r_0}^1 \Box_1\partial_r\overline{\Box}_2 + \overline{\Box}_1\partial_r\Box_2 - \Box_2\partial_r\overline{\Box}_1 - \overline{\Box}_2\partial_r\Box_1 dr &= 2\int_{r_0}^1 \Box_1\partial_r\overline{\Box}_2 + \overline{\Box}_1\partial_r\Box_2 dr \\ &\quad +[\Box_1\overline{\Box}_2 + \overline{\Box}_1\Box_2]_{r_0}, \end{aligned} \tag{251}$$

or

$$\begin{aligned} &= -2\int_{r_0}^1 \Box_2\partial_r\overline{\Box}_1 + \overline{\Box}_2\partial_r\Box_1 dr \\ &\quad -[\Box_1\overline{\Box}_2 + \overline{\Box}_1\Box_2]_{r_0}. \end{aligned} \tag{252}$$

In both these expressions the boundary term at $r = 1$ (i.e. at $\partial\mathcal{N}$) vanishes because δe_{ij} and thus $\Box_2$ and $\overline{\Box}_2$ vanish on $\partial\mathcal{N}$.

$C[\{\mu(1),\cdot\}_\circ,\delta]$ can be put in a form that facilitates the solution of (201) by integrating the contribution of $\mathcal{N}_R$ by parts one way, according to (252), and the contribution of $\mathcal{N}_L$ the other way, according to (251). For variations δ satisfying $0 = \delta\rho_0 = \delta s_R = \delta s_L$ the surface terms of the two contributions then cancel: By (249) and (245)

$$\Box_1\overline{\Box}_2 + \overline{\Box}_1\Box_2 = \frac{\rho_y}{(1-|\mu|^2)^2}[\delta_1\mu\delta_2\bar{\mu} + \delta_1\bar{\mu}\delta_2\mu] \tag{253}$$

$$= -\frac{1}{4}\rho_y\delta_1 e_{ij}\delta_2 e^{ij}. \tag{254}$$

Since both $\delta_1 = \{\mu(1), \cdot\}_\circ$ and $\delta_2 = \delta$ leave ρ_0, y_R and y_L invariant $\delta_1^{a_R} = \delta_1^b = \delta_1^{a_L}$ and $\delta_2^{a_R} = \delta_2^b = \delta_2^{a_L}$. The fact that δ_1 and δ_2 both respect the constraint (109) thus implies that

$$\int_{S_0} \rho_{y\,R}\, \delta_1^{a_R} e_{R\,ij}\, \delta_2^{a_R} e_R{}^{ij}\, dy_R^1 \wedge dy_R^2 = \int_{S_0} \rho_{y\,L}\, \delta_1^{a_L} e_{L\,mn}\, \delta_2^{a_L} e_L{}^{mn}\, dy_L^1 \wedge dy_L^2. \qquad (255)$$

That is, the surface terms cancel and

$$\begin{aligned} C[\{\mu(1), \cdot\}_\circ, \delta] = \frac{1}{4\pi G}[\quad &+ \int_{S_R} dy_R^1 \wedge dy_R^2 \int_{r_0}^1 \Box_{R\,2} \partial_r \overline{\Box}_{R\,1} + \overline{\Box}_{R\,2} \partial_r \Box_{R\,1} dr \\ &- \int_{S_L} dy_L^1 \wedge dy_L^2 \int_{r_0}^1 \Box_{L\,1} \partial_r \overline{\Box}_{L\,2} + \overline{\Box}_{L\,1} \partial_r \Box_{L\,2} dr]. \end{aligned} \qquad (256)$$

(Further on we shall need to evaluate $C[\{\mu(1), \cdot\}_\circ, \delta]$ for arbitrary admissible δ. It is therefore worth noting that (250), (251), (252), and (254) hold for *all* admissible δ.)

We are now ready to solve

$$\delta\mu(1) = \hat{\Omega}[\{\mu(1), \cdot\}_\circ, \delta] \qquad (257)$$

for $\{\mu(1), \mu(2)\}_\circ$ and $\{\mu(1), \bar{\mu}(2)\}_\circ$. Since $1 \in \mathcal{N}_R - S_0$ our causality requirement implies that both these brackets vanish when $2 \in \mathcal{N}_L - S_0$, because 2 is then outside the causal domain of influence, $J[1]$, of 1. (See appendix B prop. B.7). Thus in the second term of (256), the contribution of $\mathcal{N}_L$, $\Box_{L\,1}$ and $\overline{\Box}_{L\,1}$ can have support only on S_0 itself. Could they be singular distributions supported there? $\delta\mu_L$ and $\delta\bar{\mu}_L$ (and therefore $\partial_r \Box_{L\,2}$ and $\partial_r \overline{\Box}_{L\,2}$) can be varied freely in a neighbourhood of S_0 in $\mathcal{N}_L$.[70] Moreover, both are independent of $\delta\mu(1)$. It follows that $\Box_{L\,1}$ and $\overline{\Box}_{L\,1}$ must vanish as distributions on $\mathcal{N}_L - \partial\mathcal{N}$, and that the contribution of $\mathcal{N}_L$ to (256) vanishes.

On $\mathcal{N}_R$ $\Box_{R\,2}$ and $\overline{\Box}_{R\,2}$ are freely variable except that they must vanish on $\partial\mathcal{N}$. Thus (257) requires that

$$\partial_r \Box_{R\,1} = 0 \qquad (258)$$

and

$$\frac{\sqrt{\rho_y}\, e^\alpha}{1 - |\mu|^2} \partial_r \overline{\Box}_{R\,1} = 4\pi G \delta^2(y - y(1)) \delta(r - r(1)) \sigma \qquad (259)$$

as distributions on $\mathcal{N}_R - \partial\mathcal{N}$. Here σ is $+1$ if r increases away from S_0 (i.e. if $r_0 < 1$) and -1 if r decreases away from S_0 ($r_0 > 1$). This factor must be inserted because the integral over an interval $[a, b]$ of a delta distribution with support between a and b is $+1$ if $b > a$ and -1 if $b < a$.

[70] $\delta\mu_L$ and $\delta\bar{\mu}_L$ are not independent since one is the complex conjugate of the other, but they are *linearly* independent, that is no non-zero pair of constants a, b exist such that at a given point $a\delta\mu_L + b\delta\bar{\mu}_L = 0$ for all possible variations. This is sufficient for our purposes.

(258) and (259) are satisfied by

$$\{\mu(1),\mu(2)\}_\circ = 0 \tag{260}$$

$$\{\mu(1),\bar\mu(2)\}_\circ = 2\pi G\,\delta^2(y(2)-y(1))\,sgn(r(2)-r(1))\sigma \\ [\frac{1-|\mu|^2}{\sqrt{\rho_y}}]_1[\frac{1-|\mu|^2}{\sqrt{\rho_y}}]_2\, e^{\int_{r(1)}^{r(2)}\frac{1}{1-|\mu|^2}[\bar\mu\partial_r\mu-\mu\partial_r\bar\mu]dr} \tag{261}$$

for $1\in\mathcal{N}_R-S_0$ and $2\in\mathcal{N}_R$, where

$$sgn(r(2)-r(1)) = \begin{cases} +1 & \text{if } r(2)>r(1) \\ -1 & \text{if } r(2)<r(1) \end{cases} \tag{262}$$

Notice that when 1 and 2 lie on the same generator $sgn(r(2)-r(1))\sigma = sgn(1,2)$ and that $\int_{r(1)}^{r(2)}\frac{1}{1-|\mu|^2}[\bar\mu\partial_r\mu-\mu\partial_r\bar\mu]dr = \int_1^2\frac{1}{1-|\mu|^2}[\bar\mu d\mu-\mu d\bar\mu]$, so (261) differs from (218) only in that the y_R chart is used to label the generators instead of the θ chart.

These brackets are not the only possible solutions to (257). (258) and (259) allow the addition of functions independent of r to $\Box_{R1}$ and to $\overline{\Box}_{R1}$. The requirement that the brackets be antisymmetric reduces this freedom. In the case of $\{\mu(1),\mu(2)\}_\circ$ it eliminates the ambiguity all together - (260) is the only possibility. In the case of $\{\mu(1),\bar\mu(2)\}_\circ$ one is still free to replace $\delta^2(y(2)-y(1))\,sgn(r(2)-r(1))\sigma$ in 261 by $\delta^2(y(2)-y(1))\,sgn(r(2)-r(1))\sigma + i\Upsilon(y(1),y(2))$, where Υ is real. Causality requires that Υ is a singular distribution with support only on $y(1)=y(2)$, and covariance under transformations of the y coordinates requires that it transforms as $\delta^2(y(2)-y(1))$ does. Some possibilities are Υ = constant $\times\,\delta^2(y(2)-y(1))$ or $\Upsilon=\lambda(y)\times\delta^2(y(2)-y(1))$.

The freedom in the bracket $\{\mu(1),\bar\mu(2)\}_\circ$ propagates to other brackets. Here the simplest bracket, with $\Upsilon=0$, will be adopted since it seems the simplest and most natural seeming choice.

What about the brackets between μ_R on $\mathcal{N}_R-S_0$ and μ_L and $\bar\mu_L$ on $\mathcal{N}_L$? Causality and the constraint (109) imply that

$$\{\mu_R(1),\mu_L(2)\}_\circ = 0 \tag{263}$$

$$\{\mu_R(1),\bar\mu_L(2)\}_\circ = \begin{cases} [\frac{\partial\bar\mu_L}{\partial\bar\mu_R}]_2\{\mu_R(1),\bar\mu_R(2))\}_\circ & \text{for } 2\in S_0 \\ 0 & \text{for } 2\in\mathcal{N}_L-S_0 \end{cases} \tag{264}$$

The case $2\in S_0$ requires explanation. In this case the constraint (109) implies that $\mu_L(2)$ may be expressed as a function of $\mu_R(2)$, and the coordinate transformation from the complex coordinate $z_R=y_R^1+iy_R^2$ to $z_L=y_L^1+iy_L^2$:

$$\mu_L(\mu_R) = [\frac{\partial z_R}{\partial\bar z_L}+\mu_R\frac{\partial\bar z_R}{\partial\bar z_L}]/[\frac{\partial z_R}{\partial z_L}+\mu_R\frac{\partial\bar z_R}{\partial z_L}], \tag{265}$$

(see (212)). Similarly $\bar{\mu}_L$ may be expressed in terms of $\bar{\mu}_R$, and the coordinate transformation, via the formal complex conjugate of (265). Since $\mu_R(1)$ commutes with μ_R, s_L, s_R and ρ_0

$$\{\mu_R(1), \mu_L(\mu_R; 2)\}_\circ = 0 \tag{266}$$

and

$$\{\mu_R(1), \bar{\mu}_L(\bar{\mu}_R; 2)\}_\circ = [\frac{\partial \bar{\mu}_L}{\partial \bar{\mu}_R}]_2 \{\mu_R(1), \bar{\mu}_R(2))\}_\circ. \tag{267}$$

(Note that we are using the fact that by (265) μ_L depends only on μ_R and the coordinate transformation, and not on $\bar{\mu}_R$.) The fact that $\{\mu_R(1), \bar{\mu}_L(2)\}_\circ$ does not vanish on all of $\mathcal{N}_L$ does not contradict the requirement that $\overline{\Box}_{L,1}$ vanishes as a distribution, for if $\overline{\Box}_{L,1}$ as defined by (264), (265), and (261) is integrated against a smooth function on $\mathcal{N}_L$ the result vanishes.

Note that although the variation of e produced by $\{\mu_R(1), \cdot\}_\circ$ is discontinuous at S_0 (264) assures that $\{\mu_R(1), \cdot\}_\circ$ respects the constraint (109), for the constraint is a requirement of consistency rather than one of continuity. The constraint requires that $e_{R\,ij}$ and $e_{L\,mn}$ define the same e_{ab} on S_0, and $\{\mu_R(1), \cdot\}_\circ$ respects this condition.

Instead of parametrizing e by μ_R on $\mathcal{N}_R$ and by μ_L on $\mathcal{N}_L$, one may parametrize e on all of $\mathcal{N}$ by μ referred to the b chart. When solving (201) we wished to use variables with vanishing variation on $\partial\mathcal{N}$ under admissible variations of the solution. However, now that we have solved (201) for the brackets between the μ and $\bar{\mu}$ fields nothing stops us from transforming these brackets into the b chart. Indeed this transformation simplifies the brackets somewhat.

To carry out the transformation first note that since the brackets of μ (and $\bar{\mu}$) with s^i_R, s^m_L, and ρ_0 vanish the transformation from the a to the b coordinates, although really field dependent, can be treated as field independent when transforming the brackets of μ and $\bar{\mu}$. Second, recall that the only difference between (261) and (218) for points on $\mathcal{N}_R$ is that in the former the y_R chart is used to label the generators while in the latter these are labelled by the θ coordinates. The same is true for the two versions, (260) and (220), of the bracket between $\mu(1)$ and $\mu(2)$ on $\mathcal{N}_R$. But we have shown that (220) and (218) are invariant under arbitrary diffeomorphisms of the θ coordinates, and thus in particular under the transformation from the θ chart to the y_R chart and *vice. versa*. Transforming (260) and (261) - and their analogs on $\mathcal{N}_L$ - to the θ chart thus yields exactly (220) and (218),

$$\begin{aligned} \{\mu(1), \mu(2)\}_\circ &= \{\bar{\mu}(1), \bar{\mu}(2)\}_\circ = 0, & (268)\\ \{\mu(1), \bar{\mu}(2)\}_\circ &= 2\pi G\, \delta^2(\theta(2) - \theta(1))\, sgn(1,2) \\ &\quad [\frac{1-|\mu|^2}{\sqrt{\rho}}]_1 [\frac{1-|\mu|^2}{\sqrt{\rho}}]_2\, e^{\int_1^2 \frac{1}{1-|\mu|^2}[\bar{\mu}d\mu - \mu d\bar{\mu}]}, & (269) \end{aligned}$$

for points 1 and 2 belonging to the same branch of $\mathcal{N}$ with at most one of these lying on S_0. (263) and (264) show that the brackets between these fields at points 1 and 2 belonging to distinct branches, with neither lying on S_0, vanishes. If (268) and (269) hold then the formulae (263) and (264) for the brackets of $\mu_R(1)$ with $\mu_L(2)$ and $\bar{\mu}_L(2)$ for $2 \in S_0$ follow as automatic consequences.

(268) and (269) also suggest values for the brackets when 1 and 2 both belong to S_0. They suggest that

$$0 = \{\mu(1), \mu(2)\}_\circ = \{\mu(1), \bar{\mu}(2)\}_\circ = \{\bar{\mu}(1), \bar{\mu}(2)\}_\circ \tag{270}$$

for $1, 2 \in S_0$. In applying (268) and (269) to the case $1, 2 \in S_0$ we are of course extrapolating. These equations have not yet been shown to be consistent with (201) in this case. Moreover, (269), which is unambiguous when $\bar{\mu}(2)$ is smeared with a smooth function on $\mathcal{N}$, is ambiguous when 1 and 2 are restricted to S_0 because the discontinuous function $sgn(1, 2)$ has not been defined except when 1 and 2 lie on the same generator. If this function is discontinuous on S_0 (which $sgn(r(2) - r(1))\sigma$ is) then the product $\delta^2(\theta(1) - \theta(2))sgn(1, 2)$ is ambiguous. We therefore need to check the compatibility of the proposed brackets (270) with (201).

As a first step let us verify that $\hat{\Omega}[\{\mu_R(1), \cdot\}_\circ, \delta] = \delta\mu_R(1)$ for $1 \in S_0$ is satisfied for admissible δ such that $\delta s^i_R = \delta s^m_L = \delta\rho_0 = 0$ provided all the expressions (260), (261), (263), and (264) for the brackets among the μ and $\bar{\mu}$ fields obtained so far, as well as the proposed brackets (270), hold.

To do this we integrate both terms in (250) by parts according to (251). Then

$$\begin{aligned} C[\{\mu_R(1), \cdot\}_\circ, \delta] = -\frac{1}{4\pi G}[& \int_{S_R} dy^1_R \wedge dy^2_R \int_{r_0}^1 \Box_{R\,1}\partial_r\overline{\Box}_{R\,2} + \overline{\Box}_{R\,1}\partial_r\Box_{R\,2}dr \\ + & \int_{S_L} dy^1_L \wedge dy^2_L \int_{r_0}^1 \Box_{L\,1}\partial_r\overline{\Box}_{L\,2} + \overline{\Box}_{L\,1}\partial_r\Box_{L\,2}dr \\ + \tfrac{1}{2} & \int_{S_0} dy^1_R \wedge dy^2_R \,(\Box_{R\,1}\overline{\Box}_{R\,2} + \overline{\Box}_{R\,1}\Box_{R\,2}) \\ + \tfrac{1}{2} & \int_{S_0} dy^1_L \wedge dy^2_L \,(\Box_{L\,1}\overline{\Box}_{L\,2} + \overline{\Box}_{L\,1}\Box_{L\,2})]. \end{aligned} \tag{271}$$

(Recall that $\Box_1$ corresponds to $\delta_1 \equiv \{\mu_R(1), \cdot\}_\circ$ and $\Box_2$ to $\delta_2 \equiv \delta$.)

By (270) the S_0 integrals vanish. (260) and its analog for $\mathcal{N}_L$ imply that

$$\Box_{R\,1} = \Box_{L\,1} = 0 \tag{272}$$

and (261) implies that[71]

$$\overline{\Box}_{R\,1} \;=\; \left[\frac{\sqrt{\rho_y}\, e^{-\alpha}}{1 - |\mu|^2}\right]_R \{\mu_R(1), \bar{\mu}_R\}_\circ \tag{273}$$

[71] Recall that $\overline{\Box}$ is need not be the complex conjugate of $\Box$.

$$= \quad 2\pi G \left[\frac{1-|\mu|^2}{\sqrt{\rho_y}}\right]_{1\,R} \delta^2(y_R - y_R(1)) \tag{274}$$

on $\mathcal{N}_R - S_0$, and (270) implies that it is zero on S_0 itself. Therefore

$$\begin{aligned}
&-\int_{S_R} dy^1_R \wedge dy^2_R \int_{r_0}^1 \Box_{R1}\partial_r \overline{\Box}_{R2} + \overline{\Box}_{R1}\partial_r \Box_{R2}\, dr \\
&= \quad -2\pi G \left[\frac{1-|\mu|^2}{\sqrt{\rho_y}}\right]_{1\,R} [\int_{r_0}^1 \partial_r \Box_{R2}\, dr]_{y=y(1)} && (275)\\
&= \quad 2\pi G \left[\frac{1-|\mu|^2}{\sqrt{\rho_y}}\right]_{1\,R} \Box_{R2}(r_0) && (276)\\
&= \quad 2\pi G\, \delta^{a_R}\mu_R(1). && (277)
\end{aligned}$$

Similarly, at any point of $\mathcal{N}_L$

$$\overline{\Box}_{L1} = \left[\frac{\sqrt{\rho_y}\, e^{-\alpha}}{1-|\mu|^2}\right]_L \{\mu_R(1), \bar{\mu}_L\}_\circ \tag{278}$$

The bracket $\{\mu_R(1), \bar{\mu}_L(2)\}_\circ$ with $1 \in S_0$ and $2 \in \mathcal{N}_L - S_0$ may be evaluated using the complex conjugate of the analog for $\mathcal{N}_L$ of (264), yielding

$$\overline{\Box}_{L1} = \left[\frac{\sqrt{\rho_y}\, e^{-\alpha}}{1-|\mu|^2}\right]_L \left[\frac{\partial \mu_R}{\partial \mu_L}\right]_1 \{\mu_L(1), \bar{\mu}_L\}_\circ. \tag{279}$$

It follows, by the analog of the calculation carried out in (274 - 277), that

$$\begin{aligned}
-\int_{S_L} dy^1_L \wedge dy^2_L \int_{r_0}^1 \Box_{L1}\partial_r \overline{\Box}_{L2} + \overline{\Box}_{L1}\partial_r \Box_{L2}\, dr \quad &= \quad 2\pi G\, [\frac{\partial \mu_R}{\partial \mu_L}]_1 \delta^{a_L}\mu_L(1) && (280)\\
&= \quad 2\pi G\, \delta^{a_L}\mu_R(1). && (281)
\end{aligned}$$

$\delta^{a_L}\mu_R(1)$ is $\delta^{a_L}\mu$ evaluated in the a_R chart at the values $a^\alpha_R(1)$ of the a_R coordinates. By (212) μ transforms autonomously under change of coordinates, i.e. μ in the new chart depends only on μ in the old chart and on the transformation between the charts - it does not depend on other fields, such as $\bar{\mu}$, in the old coordinates. $\delta^{a_L}\mu_R(1)$ is thus defined by (125). This definition implies that

$$\delta^{a_L}\mu_R = \partial \mu_R / \partial \mu_L \delta^{a_L}\mu_L, \tag{282}$$

where in the partial derivative μ_R is μ referred to to the *fixed* chart $a_{R\,0}$ which agrees with a_R at the fiducial solution, and similarly μ_L is referred to the fixed chart $a_{L\,0}$ defined by to a_L at the fiducial solution. The partial derivative is of course evaluated at fixed $a_{L\,0}$ (and thus fixed $a_{R\,0}$).

The sum of all the terms in (271) is thus

$$\frac{1}{2}\delta^{a_R}\mu_R(1) + \frac{1}{2}\delta^{a_L}\mu_R(1). \tag{283}$$

Note that this evaluation of $C[\{\mu_R(1),\cdot\}_\circ,\delta]$ is valid for all admissible δ - the hypotheses that $\delta s^i_R = \delta s^m_L = \delta\rho_0 = 0$ have not been used. At present however we are interested in the case that these hypotheses do hold. Then $\delta^{a_R} = \delta^b = \delta^{a_L}$ and the sum (283) of the terms is $\delta\mu_R(1)$ as required. That is, with the brackets we have adopted $\hat{\Omega}[\{\mu_R(1),\cdot\}_\circ,\delta] = \delta\mu_R(1)$ for all $1 \in int\mathcal{N}$ and all admissible δ satisfying $\delta s^i_R = \delta s^m_L = \delta\rho_0 = 0$.

But of course this condition must hold also for δ such that δs^i_R, δs^m_L, and $\delta\rho_0$ are *not* all zero. Considering such variations allows us to determine the brackets between e and $\hat{\omega}_{Ri}$, $\hat{\omega}_{Lm}$, and λ.

Let us begin with the case $1 \in S_0$. Instead of working with μ_R it is somewhat more convenient to use the conformal 2-metric in θ coordinates, e_{ab}. Thus we look for brackets that verify the relation $\hat{\Omega}[\{e_{ab}(1),\cdot\}_\circ,\delta] = \delta e_{ab}(1)$.

To evaluate $\hat{\Omega}[\{e_{ab}(1),\cdot\}_\circ,\delta]$ we begin by noting that

$$B[\{e_{ab}(1),\cdot\}_\circ,\delta] = 0 \tag{284}$$

since $e_{ab}(1)$ on S_0 commutes with e on S_0 and with ρ_0, s_R, and s_L. Furthermore

$$\begin{aligned} &A[\{e_{ab}(1),\cdot\}_\circ,\delta] \\ &\quad = \frac{1}{16\pi G}\int_{S_0} 2\{e_{ab}(1),\lambda\}_\circ\delta\rho_0 + \{e_{ab}(1),\hat{\omega}_{Ri}\}_\circ\delta s^i_R + \{e_{ab}(1),\hat{\omega}_{Lm}\}_\circ\delta s^m_L\, d\theta^1\wedge d\theta^2 \end{aligned} \tag{285}$$

and we have essentially already evaluated $C[\{e_{ab}(1),\cdot\}_\circ,\delta]$. The only brackets occurring in $C[\{e_{ab}(1),\cdot\}_\circ,\delta]$ are of the form $\{e_{ab}(1),e_{A\,kl}\}_\circ$ with $A = L$ or R. e_{ab} is a function of μ_R, $\bar{\mu}_R$, and s_R and ρ_0. Therefore, since $e_{A\,kl}$ commutes with the latter two fields,

$$\{e_{ab}(1),e_{A\,kl}\}_\circ = [\frac{\partial e_{ab}}{\partial\mu_R}]_1\{\mu_R(1),e_{A\,kl}\}_\circ + \text{complex conjugate} \tag{286}$$

and thus

$$C[\{e_{ab}(1),\cdot\}_\circ,\delta] = [\frac{\partial e_{ab}}{\partial\mu_R}]_1 C[\{\mu_R(1),\cdot\}_\circ,\delta] + \text{complex conjugate}. \tag{287}$$

Now by (283)

$$C[\{\mu_R(1),\cdot\}_\circ,\delta] = \frac{1}{2}[\delta^{a_R}\mu_R + \delta^{a_L}\mu_R]_1. \tag{288}$$

Hence

$$C[\{e_{ab}(1),\cdot\}_\circ,\delta] = \frac{1}{2}[\frac{\partial e_{ab}}{\partial \mu_R}(\delta^{a_R}+\delta^{a_L})\mu_R]_1 + \text{complex conjugate.} \quad (289)$$

$$= \frac{1}{2}(\delta^{a_R}+\delta^{a_L})e_{ab}(1). \quad (290)$$

But

$$\delta^a e_{ab} = \delta^y e_{ab} - \delta^y r\partial_r e_{ab} \quad (291)$$

$$= \delta^b e_{ab} - \pounds_{\xi_\perp} e_{ab} - \frac{v}{2\rho_0}[\delta^b - \pounds_{\xi_\perp}]\rho_0\,\partial_v e_{ab}, \quad (292)$$

and

$$\pounds_{\xi_\perp}\rho_0 = \partial_c[\rho_0\xi^c_\perp], \quad (293)$$

with $\xi^i_\perp = \delta s^i$ and $v = r/r_0$ the v coordinate that parametrizes the generators of the branch under consideration. $\hat{\Omega}[\{e_{ab}(1),\cdot\}_\circ,\delta] = \delta e_{ab}(1)$ therefore requires

$$\begin{aligned} 0 = {} & [-\frac{1}{2}\pounds_{\xi_{\perp R}} e_{ab} + \frac{1}{4}\frac{\partial_c[\rho_0\xi^c_{\perp R}]}{\rho_0}\partial_{v^-}e_{ab} - \frac{1}{4}\frac{\delta^b\rho_0}{\rho_0}\partial_{v^-}e_{ab}]_1 \\ & + \frac{1}{16\pi G}\int_{S_0}\{e_{ab}(1),\lambda\}_\circ\delta\rho_0 + \{e_{ab}(1),\hat{\omega}_{Ri}\}_\circ\delta s^i_R\, d\theta^1\wedge d\theta^2 \\ & + \text{corresponding } L \text{ branch terms.} \end{aligned} \quad (294)$$

From this one obtains the brackets (225) and (226), and the L analog of the latter:

$$\{e_{ab}(1),\lambda(2)\}_\circ = 2\pi G\frac{1}{\rho_0}[\partial_{v^-}e_{ab} + \partial_{v^+}e_{ab}]\delta^2(\theta(2)-\theta(1)), \quad (295)$$

$$\{e_{ab}(1),\hat{\omega}_R[f]\}_\circ = 8\pi G[\pounds_f e_{ab} - \frac{1}{2}\partial_{v^-}e_{ab}\frac{\pounds_f\rho_0}{\rho_0}]_1, \quad (296)$$

$$\{e_{ab}(1),\hat{\omega}_L[g]\}_\circ = 8\pi G[\pounds_g e_{ab} - \frac{1}{2}\partial_{v^+}e_{ab}\frac{\pounds_g\rho_0}{\rho_0}]_1. \quad (297)$$

Now let us consider the case $1\in\mathcal{N}_R - S_0$ again. We require

$$\hat{\Omega}[\{e_{Rij}(1),\cdot\}_\circ,\delta] = \delta e_{Rij}(1) \quad (298)$$

for all admissible variations δ. Reviewing the derivation of (256) one verifies that for general admissible δ

$$C[\{e_{Rij}(1),\cdot\}_\circ,\delta] = \delta e_{Rij}(1) - \frac{1}{32\pi G}\int_{S_0}\epsilon\{e_{Rij}(1),e^{ab}\}_\circ[\delta^{a_R}-\delta^{a_L}]e_{ab}. \quad (299)$$

The other terms in $\hat{\Omega}$ are

$$A[\{e_{Rij}(1),\cdot\}_\circ,\delta] = \frac{1}{16\pi G}\int_{S_0} 2\{e_{Rij}(1),\lambda\}_\circ\delta\rho_0 + \{e_{Rij}(1),\hat{\omega}_{Ri}\}_\circ\delta s^i_R + \{e_{Rij}(1),\hat{\omega}_{L\,m}\}_\circ\delta s^m_L\; d\theta^1\wedge d\theta^2 \tag{300}$$

and

$$B[\{e_{Rij}(1),\cdot\}_\circ,\delta] = -\frac{1}{64\pi G}\int_{S_0}\{e_{Rij}(1),e^{ab}\}_\circ[\partial_{v^-}e_{ab}\delta^{y_R}+\partial_{v^+}e_{ab}\delta^{y_L}]\epsilon. \tag{301}$$

Thus, by (292), (298) requires

$$\begin{aligned} 0 = \int_{S_0} d\theta^1\wedge d\theta^2 \quad & (2\{e_{Rij}(1),\lambda\}_\circ\delta\rho_0 \\ & +\{e_{Rij}(1),\hat{\omega}_{Rk}\}_\circ\delta s^k_R + \{e_{Rij}(1),\hat{\omega}_{L\,m}\}_\circ\delta s^m_L \\ & -\frac{1}{2}\{e_{Rij}(1),e^{ab}\}_\circ\partial_{v^+}e_{ab}\delta^{y_L}\rho_0 \\ & +\frac{1}{2}\rho_0\{e_{Rij}(1),e^{ab}\}_\circ[\pounds_{\xi_{\perp R}}-\pounds_{\xi_{\perp L}}]e_{ab}). \end{aligned} \tag{302}$$

From which it follows that

$$\{e_{Rij}(1),\lambda(2)\}_\circ = \frac{1}{4}\{e_{Rij}(1),e^{ab}(2)\}_\circ[\partial_{v^+}e_{ab}]_2, \tag{303}$$

and

$$\{e_{Rij}(1),\hat{\omega}_R[\xi_{\perp R}]\}_\circ = -\frac{1}{2}\int_{S_0}\epsilon\{e_{Rij}(1),e^{ab}\}_\circ\pounds_{\xi_{\perp R}}e_{ab} \tag{304}$$

$$\{e_{Rij}(1),\hat{\omega}_L[\xi_{\perp L}]\}_\circ = \frac{1}{2}\int_{S_0}\{e_{Rij}(1),e^{ab}\}_\circ(\epsilon\pounds_{\xi_{\perp L}}e_{ab}-\pounds_{\xi_{\perp L}}\epsilon\partial_{v^+}e_{ab}) \tag{305}$$

[Using

$$\pounds_{\xi_\perp}e_{ab} = 2D_{(a}[e_{b)c}\xi^c_\perp] - e_{ab}D_c\xi^c_\perp \tag{306}$$

(where D is the covariant derivative defined by the metric $\rho_0 e$ on S_0) and the fact that $\{e_{Rij}(1),e^{ab}\}_\circ$ vanishes on ∂S_0 for all $1\in int\mathcal{N}_R$ because ∂S_0 lies outside the causal domain of influence $J[1]$ of the point 1, the last two brackets may be shown to be equivalent to

$$\{e_{Rij}(1),\hat{\omega}_{Rk}(2)\}_\circ = [D_a[\{e_{Rij}(1),e^{ab}\}_\circ]\rho_0 e_{bc}\frac{\partial\theta^c}{\partial y^k_R}]_2 \tag{307}$$

$$\begin{aligned} \{e_{Rij}(1),\hat{\omega}_{L\,m}(2)\}_\circ = & [-D_a[\{e_{Rij}(1),e^{ab}\}_\circ]\rho_0 e_{bc}\frac{\partial\theta^c}{\partial y^m_L} \\ & +\frac{1}{2}\partial_c[\{e_{Rij}(1),e^{ab}\}_\circ\partial_{v^+}e_{ab}]\rho_0\frac{\partial\theta^c}{\partial y^m_L}]_2.\ ] \end{aligned} \tag{308}$$

The brackets of $e_{ab}(1)$ and $\mu(1)$ with $\lambda(2)$, $\hat{\omega}_R(2)$, and $\hat{\omega}_L(2)$ are easily obtained from (303), (304), and (305). They are given in (222), (223), and (224). But they do not seem to be more illuminating than the brackets found above. It is reassuring, given the non-obvious expressions for the brackets, that they ensure that $e_{R\,ij}$ commutes with $\kappa[v]$, the generator of diffeomorphisms of the θ coordinates, as it should.

The brackets obtained so far ensure the validity of (201) for φ equal to $\rho_0(1)$, $s_R(1)$, or $s_L(1)$ at any point $1 \in int S_0$ and for $\varphi = e_{ab}(1)$ (or any other representation of the conformal 2-metric) for any $1 \in int\mathcal{N}$. It remains only to impose (201) for φ equal to λ, $\hat{\omega}_R$, and $\hat{\omega}_L$.

Let us impose

$$\hat{\Omega}[\{\lambda(1), \cdot\}_\circ, \delta] = \delta\lambda(1). \tag{309}$$

The brackets that have already been determined imply that

$$\begin{aligned} A[\{\lambda(1), \cdot\}_\circ, \delta] &= \delta\lambda(1) \\ &+\frac{1}{16\pi G}\int_{S_0} 2\{\lambda(1), \lambda\}_\circ \delta\rho_0 + \{\lambda(1), \hat{\omega}_{R\,i}\}_\circ \delta s_R^i + \{\lambda(1), \hat{\omega}_{L\,m}\}_\circ \delta s_L^m \, d\theta^1 \wedge d\theta^2 \end{aligned} \tag{310}$$

and

$$\begin{aligned} & B[\{\lambda(1), \cdot\}_\circ, \delta] \\ &= -\frac{1}{8}\delta^{y_R} e^{ab}\partial_{v^-} e_{ab} - \frac{1}{8}\delta^{y_L} e^{ab}\partial_{v^+} e_{ab} \\ &\quad -\frac{1}{64\pi G}\int_{S_0} \{\lambda(1), e_{ab}\}_\circ (\partial_{v^-} e^{ab}\delta^{y_R}\epsilon + \partial_{v^+} e^{ab}\delta^{y_L}\epsilon) \qquad (311) \\ &= -\frac{1}{8}\delta^{y_R} e^{ab}\partial_{v^-} e_{ab} - \frac{1}{8}\delta^{y_L} e^{ab}\partial_{v^+} e_{ab} \\ &\quad +\frac{1}{32}(\partial_{v^-} e^{ab} + \partial_{v^+} e^{ab})(\partial_{v^-} e^{ab}\frac{\delta^{y_R}\rho_0}{\rho_0} + \partial_{v^+} e^{ab}\frac{\delta^{y_L}\rho_0}{\rho_0}). \qquad (312) \end{aligned}$$

Evaluating C requires a little more thought. No derivatives of $\Box_1$ appear in the expression (271) for $C[\delta_1, \delta_2]$. The bulk term in this form of $C[\{\lambda(1), \cdot\}_\circ, \delta]$ may thus be evaluated using the expression (303) for $\{\lambda(1), e_{R\,ij}(2)\}_\circ$, valid when $2 \in \mathcal{N}_R - S_0$, and the analogous expression corresponding to the L branch - ignoring the jump discontinuity in these brackets at S_0. Thus

$$C_{bulk}[\{\lambda(1), \cdot\}_\circ, \delta] = \frac{1}{4}[\partial_{v^+} e^{ab}]_1 C_{R\,bulk}[\{e_{ab}(1), \cdot\}_\circ, \delta] + \frac{1}{4}[\partial_{v^-} e^{ab}]_1 C_{L\,bulk}[\{e_{ab}(1), \cdot\}_\circ, \delta]. \tag{313}$$

But by (277) and (281)

$$C_{R\,bulk}[\{e_{ab}(1), \cdot\}_\circ, \delta] \;=\; \frac{1}{2}\delta^{a_R} e_{ab}, \tag{314}$$

$$C_{L\,bulk}[\{e_{ab}(1),\cdot\}_\circ,\delta] \;=\; \frac{1}{2}\delta^{a_L}e_{ab}, \tag{315}$$

so

$$C_{bulk}[\{\lambda(1),\cdot\}_\circ,\delta] = \frac{1}{8}\partial_{v^+}e^{ab}\delta^{a_R}e_{ab}(1) + \frac{1}{8}\partial_{v^-}e^{ab}\delta^{a_L}e_{ab}(1). \tag{316}$$

The S_0 surface contribution to C in the form (271) is

$$C_{S_0}[\delta_1,\delta_2] \;\equiv\; -\frac{1}{8\pi G}\int_{S_0} dy^1_R\wedge dy^2_R\,(\Box_{R\,1}\overline{\Box}_{R\,2}+\overline{\Box}_{R\,1}\Box_{R\,2}) + dy^1_L\wedge dy^2_L\,(\Box_{L\,1}\overline{\Box}_{L\,2}+\overline{\Box}_{L\,1}\Box_{L\,2}) \tag{317}$$

$$= \frac{1}{32\pi G}\int_{S_0}\epsilon[\delta_1^{a_R}e_{ab}\,\delta_2^{a_R}e^{ab}+\delta_1^{a_L}e_{ab}\,\delta_2^{a_L}e^{ab}] \tag{318}$$

Now if $\delta_1=\{\lambda(1),\cdot\}_\circ$ then by (292)

$$\delta_1^a e_{ab} = \{\lambda(1),e_{ab}\}_\circ - \frac{1}{2\rho_0}\{\lambda(1),\rho_0\}_\circ\,\partial_v e_{ab} \tag{319}$$

(because $\{\lambda(1),s^i\}_\circ=0$). Substituting the expressions (225) and (213) for these brackets one obtains

$$\delta_1^{a_R}e_{ab} = 2\pi G\frac{1}{\rho_0}[\partial_{v^-}e_{ab}-\partial_{v^+}e_{ab}]\delta^2(\theta(2)-\theta(1)) = -\delta_1^{a_L}e_{ab}. \tag{320}$$

Hence

$$C_{S_0}[\{\lambda(1),\cdot\}_\circ,\delta] = \frac{1}{16}[\partial_{v^-}e_{ab}-\partial_{v^+}e_{ab}](\delta^{a_R}-\delta^{a_L})e^{ab}. \tag{321}$$

Summing all the contributions, taking into account (292) and various cancellations, one finds

$$\begin{aligned}\hat\Omega[\{\lambda(1),\cdot\}_\circ,\delta] \;=\;& \delta\lambda(1)+\frac{1}{8\pi G}\int_{S_0}\{\lambda(1),\lambda\}_\circ\delta\rho_0\,d\theta^1\wedge d\theta^2\\ &+\frac{1}{16\pi G}\{\lambda(1),\hat\omega_R[\xi_{\perp R}]\}_\circ+\frac{1}{16\pi G}\{\lambda(1),\hat\omega_L[\xi_{\perp L}]\}_\circ\\ &+\frac{1}{16}[\partial_{v^-}e^{ab}-\partial_{v^+}e^{ab}]_1(\pounds_{\xi_{\perp R}}e_{ab}-\pounds_{\xi_{\perp L}}e_{ab})_1\end{aligned} \tag{322}$$

(since $\delta s^i_R=\xi^i_{\perp R}$ and $\delta s^m_L=\xi^m_{\perp L}$).

The requirement (309) thus implies that

$$\{\lambda(1),\lambda(2)\}_\circ \;=\; 0 \tag{323}$$

$$\{\lambda(1),\hat\omega_R[f]\}_\circ \;=\; -\pi G[(\partial_{v^-}e^{ab}-\partial_{v^+}e^{ab})\pounds_f e_{ab}]_1 \tag{324}$$

$$\{\lambda(1),\hat\omega_L[g]\}_\circ \;=\; -\pi G[(\partial_{v^+}e^{ab}-\partial_{v^-}e^{ab})\pounds_g e_{ab}]_1 \tag{325}$$

It remains only to impose

$$\hat{\Omega}[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] = \delta\hat{\omega}_R[f], \tag{326}$$

and the analogous equation for $\hat{\omega}_L[g]$. Our method will be closely analogous to that used to solve the condition (309) corresponding to $\lambda(1)$: First note that by (324)

$$\begin{aligned} A[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] = \delta\hat{\omega}_R[f] \; &+\frac{1}{8}\int_{S_0} \pounds_f e_{ab}(\partial_{v^-}e^{ab} - \partial_{v^+}e^{ab})\delta\epsilon \\ &-\frac{1}{16\pi G}\{\hat{\omega}_R[f],\hat{\omega}_R[\xi_{\perp R}]\}_\circ - \frac{1}{16\pi G}\{\hat{\omega}_R[f],\hat{\omega}_L[\xi_{\perp L}]\}_\circ \end{aligned} \tag{327}$$

To evaluate the B contribution recall that $\delta^y = \delta^b - \pounds_{\xi_\perp}$ with $\xi^i_\perp = \delta s^i$. Thus

$$\begin{aligned} B_R[\delta_1,\delta_2] &= -\frac{1}{64\pi G}\int_{S_0} \delta^y_1 e_{ab}\partial_{v^-}e^{ab}\delta^y_2\epsilon - (1\leftrightarrow 2) && (328)\\ &= -\frac{1}{64\pi G}\int_{S_0} \delta_1 e_{ab}\partial_{v^-}e^{ab}\delta^y_2\epsilon - \pounds_{\xi_{\perp R}1} e_{ab}\partial_{v^-}e^{ab}\delta^y_2\epsilon \\ &\qquad -\delta_1\epsilon\partial_{v^-}e^{ab}\delta^y_2 e_{ab} + \pounds_{\xi_{\perp R}1}\epsilon\partial_{v^-}e^{ab}\delta^y_2 e_{ab} && (329)\end{aligned}$$

and, by (296), (214), and (292),

$$\begin{aligned} &B[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] \\ &= -\frac{1}{64\pi G}\int_{S_0}\{\hat{\omega}_R[f],e_{ab}\}_\circ(\partial_{v^-}e^{ab}\delta^{y_R}\epsilon + \partial_{v^+}e^{ab}\delta^{y_L}\epsilon) \\ &\qquad +\frac{1}{4}\int_{S_0}(\pounds_f\epsilon\partial_{v^-}e^{ab}\delta^{y_R}e_{ab} - \pounds_f e_{ab}\partial_{v^-}e^{ab}\delta^{y_R}\epsilon) && (330)\\ &= -\frac{1}{8}\int_{S_0}[\pounds_f e_{ab} - \frac{1}{2}\partial_{v^-}e_{ab}\frac{\pounds_f\rho_0}{\rho_0}](\partial_{v^-}e^{ab}\delta^{y_R}\epsilon - \partial_{v^+}e^{ab}\delta^{y_L}\epsilon) \\ &\qquad +\frac{1}{4}\int_{S_0}\pounds_f\epsilon\partial_{v^-}e^{ab}\delta^{a_R}e_{ab} && (331)\end{aligned}$$

The contribution from C is obtained as in the evaluation of $C[\{\lambda(1),\cdot\}_\circ,\delta]$, by expanding C in bulk and surface terms according to (271) and noting that the bracket (304) and the analog of (305) with L and R interchanged imply

$$\begin{aligned} C_{bulk}[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] &= -\frac{1}{2}\int_{S_0}\epsilon\pounds_f e_{ab}C_{R\,bulk}[\{e^{ab},\cdot\}_\circ,\delta] \\ &\qquad +\frac{1}{2}\int_{S_0}(\epsilon\pounds_f e_{ab} - \pounds_f\epsilon\partial_{v^-}e_{ab})C_{L\,bulk}[\{e^{ab},\cdot\}_\circ,\delta], \end{aligned} \tag{332}$$

and therefore taking into account (314) and (315),

$$C_{bulk}[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] = -\frac{1}{4}\int_{S_0}\epsilon \pounds_f e_{ab}(\delta^{a_R}-\delta^{a_L})e^{ab} + \pounds_f\epsilon\partial_{v^-}e_{ab}\delta^{a_L}e^{ab} \tag{333}$$

There remains the surface term $C_{S_0}[\{\hat{\omega}_R[f]\cdot\}_\circ,\delta]$ to evaluate. $C_{S_0}[\delta_1,\delta_2]$ is defined by (318). If $\delta_1 = \{\hat{\omega}_R[f],\cdot\}_\circ$ then, because $\hat{\omega}_R$ commutes with ρ_0 and s_L, $\delta_1^{a_L} = \delta_1^b$ and thus, by (296)

$$\delta_1^{a_L}e_{ab} = \{\hat{\omega}_R[f], e_{ab}\}_\circ = -8\pi G[\pounds_f e_{ab} - \frac{1}{2}\frac{\pounds_f\rho_0}{\rho_0}\partial_{v^-}e_{ab}]. \tag{334}$$

$\delta_1^{a_R}$, on the other hand, differs from δ_1^b. By (292), (214), and (296)

$$\begin{aligned}\delta_1^{a_R}e_{ab} &= \{\hat{\omega}_R[f], e_{ab}\}_\circ + 16\pi G[\pounds_f e_{ab} - \frac{1}{2}\frac{\pounds_f\rho_0}{\rho_0}\partial_{v^-}e_{ab}] &(335)\\ &= -\delta_1^{a_L}e_{ab}. &(336)\end{aligned}$$

Thus

$$C_{S_0}[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] = \frac{1}{4}\int_{S_0}[\epsilon\pounds_f e_{ab} - \frac{1}{2}\pounds_f\epsilon\partial_{v^-}e_{ab}](\delta^{a_R}-\delta^{a_L})e^{ab}. \tag{337}$$

Summing this surface term and the bulk term one finds

$$C[\{\hat{\omega}_{Ri}(1),\cdot\}_\circ,\delta] = -\frac{1}{8}\int_{S_0}\pounds_f\epsilon\partial_{v^-}e_{ab}(\delta^{a_R}+\delta^{a_L})e^{ab}. \tag{338}$$

Summing A, B, and C one is left, after some cancellations, with

$$\begin{aligned}\hat{\Omega}[\{\hat{\omega}_R[f],\cdot\}_\circ,\delta] &= \delta\hat{\omega}_R[f] + \frac{1}{16\pi G}\{\hat{\omega}_R[f],\hat{\omega}_R[\xi_{\perp R}]\}_\circ + \frac{1}{16\pi G}\{\hat{\omega}_R[f],\hat{\omega}_L[\xi_{\perp L}]\}_\circ\\ &\quad +\frac{1}{8}\int_{S_0}\pounds_f e_{ab}(\partial_{v^-}e^{ab}\pounds_{\xi_{\perp R}}\epsilon - \partial_{v^+}e^{ab}\pounds_{\xi_{\perp L}}\epsilon)\\ &\quad -\frac{1}{8}\int_{S_0}\pounds_f\epsilon\partial_{v^-}e^{ab}(\pounds_{\xi_{\perp R}}e_{ab} - \pounds_{\xi_{\perp L}}e_{ab}). &(339)\end{aligned}$$

Thus

$$\begin{aligned}\{\hat{\omega}_R[f_1],\hat{\omega}_R[f_2]\}_\circ &= -2\pi G\int_{S_0}\pounds_{f_1}e_{ab}\,\partial_{v^-}e^{ab}\pounds_{f_2}\epsilon - (1\leftrightarrow 2) &(340)\\ \{\hat{\omega}_R[f],\hat{\omega}_L[g]\}_\circ &= 2\pi G\int_{S_0}[\pounds_f e_{ab}\partial_{v^+}e^{ab}\pounds_g\epsilon - \pounds_g e_{ab}\partial_{v^-}e^{ab}\pounds_f\epsilon]. &(341)\end{aligned}$$

Interchanging the roles of $\mathcal{N}_R$ and $\mathcal{N}_L$ gives us the L branch analog of (340) and the same expression (341) for $\{\hat{\omega}_R[f],\hat{\omega}_L[g]\}_\circ$ again.

With these brackets $\hat{\Omega}[\{\varphi,\cdot\}_\circ,\delta] = \delta\varphi$ for all initial data φ and all admissible δ. That is $\{\cdot,\cdot\}_\circ$ satisfies (201).

6 Concluding Remarks

We have found a fairly complete canonical formalism for the gravitational field on the domain of dependence of a single pair of intersecting null hypersurfaces. The phase space has been defined and a simple representation of this space in terms of metric fields on $\mathbb{R}^4$ has been given; the Poisson bracket has been defined on a class of "nice" phase space functions, called "observables", and most importantly, a bracket, compatible with the Poisson bracket on the observables, has been defined on a set of free initial data variables.

Several things remain to be done. The most important are:

- Resolve the problem of the Jacobi relations for the bracket on the initial data. The bracket on initial data proposed here does not satisfy the Jacobi relations, which precludes a conventional Dirac quatization of the initial data. The requirement that the bracket on initial data reproduce the (Peierls) Poisson bracket when applied to the observables leaves some freedom in the choice of bracket on the initial data. One could try to exploit this freedom to find a new bracket on the initial data which does satisfy the Jacobi relations. A hope is that this would also lead to brackets that are simpler than the ones found here.

  I am currently working along these lines, and at the time of writing it looks like it will work. If, on the other hand, no such bracket exists, this would also be interesting. That the quantum commutators should reproduce the Peierls bracket on the observables seems an eminently reasonable requirement. If there is no corresponding bracket satisfying the Jacobi relation on the initial data, then this would indicate that the initial data are not quantized in the usual sense, and some generalization of Dirac quantization is called for.

- Define a canonical theory for the whole Universe. The current form of the theory provides a canonical description of the domain of dependence of a single hypersurface $\mathcal{N}$, which never constitutes all of an inextendible solution of Einstein's field equations. One way to describe all of spacetime is to use an "atlas" of interrelated phase spaces corresponding to a covering of the spacetime by domains of dependence of the type we have considered. A state of this global theory would consist of points in each of a collection of phase spaces, and a specification of how the corresponding initial data hypersurfaces, all of the form of $\mathcal{N}$, intersect. Of course there would then be many ways to describe the same spacetime corresponding to differently positioned initial data hypersurfaces, and one would need to define the action on the phase points corresponding to a displacement of one of the initial data hypersurfaces with respect to the others. This action seems to be generated by a sort of Hamiltonian, which is currently being studied.

The multi-phase space formalism outlined seems very attractive and naturally adapted to the local nature of general relativity. In particular it does not seem to impose the global causality restriction that a theory based on global Cauchy surfaces does. This restriction does correspond to conventional ideas about time, but it is alien to general relativity and perhaps simply realizes a prejudice we have acquired in our (nearly) Minkowskian environment.

Of course there are a number of other, in my opinion lesser, loose ends:

- The meaning of gauge invariance it the present canonical formalism should be completely cleared up. At present it is unclear to me whether diffeomorphisms that map the end surfaces $S_L, S_R \subset \partial\mathcal{N}$ to themselves, and thus permute the generators of $\mathcal{N}_L$ and $\mathcal{N}_R$, should be treated as gauge or global symmetry transformations.

- One expects that the causality condition, which we have imposed as an ansatz on the bracket on the initial data, really is a consequence of the form of the presymplectic 2-form. This should be demonstrated if true.

- The bracket on initial data has been found assuming that the corresponding solution has no Killing vectors. The theory should be extended to solutions with Killing vectors, to the extent that this is possible. This would close a gap in the theory and make it possible to study the theory in concrete exact solutions. If no such extension is possible this would also be an interesting fact.

Finally, we have assumed at several points that our initial data on $\mathcal{N}$ define unique maximal Cauchy developments, and that the metric of this development is differentiable in the parameter of any smooth one parameter family of initial data. To my knowledge this has not been proved, although an heuristic argument has been given by Sachs [Sac62], and slightly weaker claims have been demonstrated by Rendall [Ren90], and it seems virtually certain to be true. To obtain the proofs an extension of Rendall's method seems viable.

The main motivation for the present work has been the desire to understand the holographic principle [Bec73][tHoo93][Sus95]. Susskind [Sus95] has given compelling, yet inconclusive, arguments in favour of holography based on semiclassical black hole theory. He also gave arguments supporting the conjecture that string theory is holographic, using a light front formulation of string theory. My aim has been to provide a framework in which some of these claims could be stated precisely and proved.

Given the present formalism (and the yet to be found bracket on initial data that satisfies the Jacobi relations) one is in a position to try to demonstrate a holographic limit on the dimensionality of the Hilbert space quantizing the phase space corresponding to $\mathcal{N}$ in either a full or semi-classical quantization of the initial data.

To see get an idea of how the theory might be quantized one might try to see how (and if) the AdS/CFT duality works in terms of a null canonical formulation of the bulk theory. Of course this requires an extension of the formalism, to supergravity and string theory. Indeed the present results on gravity on a null hypersurface might give insight into string theory in the light front gauge, and thus help to verify Susskind's [Sus95] conjecture that string theory is a holographic theory.

7 Acknowledgements

The present work has had a long gestation. The key calculations were carried out during a visit to the Centre de Physique Teorique in Luminy, France, and a visit to the Albert Einstein Institut in Potsdam, Germany. I would like to thank the CNRS for funding my visit to Luminy, and the group at Luminy, especially Carlo Rovelli, for the invitation and many discussions, and I would like to thank Thomas Thiemann for hosting me at the AEI. The work was completed at the Perimeter Institute in Waterloo, Canada and the Universidad de la Republica Oriental del Uruguay. I thank the group at Perimeter, especially Lee Smolin, Fotini Markopolou, Richard Epp, Janet Fesnoux and Howard Burton for inviting me and/or providing a wonderfully stimulating work environment. At the Universidad de la Republica I would like to thank especially Rodolfo Gambini for his constant support and for helpful discussions. In the course of this work I have benefited from the comments, questions, and encouragement of many other colleagues, among them Peter Aichelburg, Alejandro Perez, Jose-Antonio Zapata, Laurent Freidel, Jerzy Lewandowski, John Stachel, Alan Rendall, Helmuth Friedrich, Gonzalo Aniano, Michael Bradley, and Ingemar Bengtsson. I have used a TeX macro from the thesis of Chris Beetle to make some symbols.

This work has been partly supported by Proyecto 8049, Fondo Clemente Estable of the Ministerio de Educacion y Cultura, Uruguay.

A Definitions regarding manifolds and causal structure.

Here a number of definitions and a few propositions important to their meaning are gathered together for convenience of the reader. The definitions are mostly taken from [Wald84] or [HE73], or equivalent to the ones given there, but the definitions of Cauchy surfaces and developments are slightly modified. The definitions given here do not form a self-contained logical structure. A complete exposition can be found in [Wald84] and in [HE73].

A manifold will be defined as in [Wald84] p. 11. A manifold equipped with a non-degenerate metric will be called a metric manifold, and it will be called smooth or C^∞ if both the atlas and the metric are C^∞. Unless otherwise specified all manifolds will be assumed to be Hausdorff and paracompact. (see [HE73] and references therein).

A manifold, according to the (standard) definition of [Wald84], has only interior points. However the concept of a manifold can be generalized to that of a manifold with boundary. If such a manifold is differentiable one can distinguish in the boundary differentiable components as well as edges, corners, and in general lower dimensional "strata".

Definition A.1 *A* manifold with boundary *is defined in the same way as a manifold without boundary, except that the charts, instead of being maps to open subsets of* $\mathbb{R}^n$*, are maps to open subsets of the half space* $\frac{1}{2}\mathbb{R}^n$ *consisting of the half of* $\mathbb{R}^n$ *on which the first component,* x^1*, of each n-tuple is* ≥ 0*. The boundary* ∂Y *of a manifold with boundary* Y *is composed of the points that are mapped to* $x^1 = 0$ *by the charts.*

Differentiable manifolds generalize to *stratified manifolds* in which the charts may be maps to open subsets of the 1/4 space, 1/8 space, or $1/2^m$ space, consisting of real $n-tuples$ of which the first two, three, or m components, as the case may be, are ≥ 0. The nm dimensional strata consist of the points mapped to $0 = x^1 = x^2 = ... = x^m$ in the $1/2^m$ space by these charts. $\mathcal{N}$ is a stratified manifold. Note that according to the present definition, the boundary ∂Y of a stratified manifold includes the union of all the lower dimensional strata.

In the present work "manifold", without further qualification, will denote a C^∞ manifold with or without boundary (or lower dimensional strata). Note that a manifold *without* boundary can be the interior of a manifold with boundary. The absence of a boundary does not imply that a boundary could not be attached to the manifold, only that it is not included in it.

Now we turn to definitions associated with the causal structure defined by a smooth Lorentzian metric on a manifold X without boundary. We shall assume that X is time orientable with this metric - there is a continuous choice of the future half of the light cone throughout X. In fact, unless otherwise specified, we shall always assume that Lorentzian metric manifolds representing spacetime are time orientable. Furthermore we shall assume that spacetime is 4 dimensional. However most definitions and results generalize in an obvious way to spacetimes of any dimensionality.

Definition A.2 *The* causal future*,* $J^+[S;X]$*, of a set* $S \subset X$ *in* X *is the set of points of* X *that can be reached from some point in the set* S *via a future directed differentiable causal curve in* X *- a curve with tangent everywhere null or timelike.*

Definition A.3 *The* chronological future*, $I^+[S;X]$, of a set $S \subset X$ in X is the set of points of X that can be reached from some point in S via a future directed differentiable timelike curve in X of non-zero duration - a curve with tangent everywhere non-zero and timelike.*

Definition A.4 *The* future domain of dependence *$D^+[S;X]$ of $S \subset X$ in X is the set of points $p \in X$ such that all inextendible causal curves in X from p intersect S to the past of p.*

(Often, when the ambient spacetime manifold with respect to which these sets are defined is clear from the context, it will not be specified explicitly, and we shall write $I^+[S]$, $J^+[S]$, and $D^+[S]$.)

The definitions of the causal past J^-, chronological past I^-, and past domain of dependence D^- are the obvious time reversed analogs of those of J^+, I^+, and D^+.

Uniting the past and future parts one may define the full *domain of dependence* as $D[S] = D^+[S] \cup D^-[S]$, the *causal domain of influence* as $J[S] = J^+[S] \cup J^-[S]$, and the *chronological domain of influence* as $I[S] = I^+[S] \cup I^-[S]$. $D[S]$ may be defined directly as the set of points $p \in X$ such that all inextendible causal curves in X through p intersect S (to the past or to the future of p). While $J[S]$ and $I[S]$ are the unions of the causal and timelike curves through S respectively.

Definition A.5 *A subset S of X is* achronal *iff no timelike curve in X crosses S more than once, i.e. at two or more values of the curve's parameter.*

Equivalently, S is achronal iff S, $I^+[S]$, and $I^-[S]$ are disjoint.

The achronality of a set requires that its interior, suitably defined, be an embedded 3-manifold: If S is achronal then S is disjoint from $I^+[S]$, but of course $S \subset \bar{I}^+[S]$. Thus $S \subset \dot{I}^+[S]$. But by prop. 6.3.1. of [HE73] $\dot{I}^+[S]$ is a C^{1-},[72] embedded 3-manifold. If the *interior* of S, *int*S, is defined to be the topological interior of S in $\dot{I}^+[S]$, then *int*S is also a C^{1-}, embedded 3-dimensional submanifold (without boundary). Note that *int*S is *not* the interior of S in the ambient spacetime X, which is empty.

This makes possible a more intrinsic definition of *int*S:

Definition A.6 *The* interior*, int$S$ of an achronal subset $S \subset X$ is the largest subset of S that is an embedded 3-submanifold of X without boundary. (Equivalently it is the union of all such subsets).*

The equivalence of this definition with the earlier one can be deduced from the following topological lemma:

[72] It satisfies a Lipschitz condition, and *a fortiori* is C^0. See [HE73].

Lemma A.1 *If A is an n-manifold with boundary embedded in a n-manifold without boundary B, then $A - \partial A$, the interior of A according to its structure as a manifold with boundary, equals $A - \dot{A}$, the interior of A in the topology of B, and $\partial A \subset \dot{A}$.*

Proof: A point $p \in A$ lies in the domain of a chart $\psi : V \rightarrow_{\frac{1}{2}} \mathbb{R}^n$ of A and a chart $\phi : V' \rightarrow \mathbb{R}^n$ with V and V' open neighbourhoods of p in A and B respectively. If U is an open neighbourhood of p in A which is contained in both V and V' then $\phi \circ \psi^{-1}$ is a homeomorphism from $\psi[U]$, an open subset of $\frac{1}{2}\mathbb{R}^n$, to the subset $\phi[U]$ of $\mathbb{R}^n$.

Suppose $p \in \partial A$. $\psi[U] \subset_{\frac{1}{2}} \mathbb{R}^n$ cannot then be open in $\mathbb{R}^n$, because it contains $\psi(p)$ which lies on the boundary of $\frac{1}{2}\mathbb{R}^n$ in the topology of $\mathbb{R}^n$. On the other hand, since A is an embedded submanifold with boundary the open sets of A are the intersections of A with open sets of B. Thus there exists a set U' open in B such that $U = U' \cap A$. $\phi[U']$ is open in $\mathbb{R}^n$. Brouwer's invariance of domain theorem [Bro12] requires that the homeomorphic image in $\mathbb{R}^n$ of an open set in $\mathbb{R}^n$ be open.[73] The open set $\phi[U']$ thus cannot be homeomorphic to $\psi[U]$, and therefore not to $\phi[U] = \phi[U' \cap A]$ either. U must contain a point outside A. It follows that $p \in \dot{A}$, and hence that $\partial A \subset \dot{A}$.

Now suppose that, on the contrary, $p \in A - \partial A$. Then $\psi(p)$ does not lie in the boundary plane of $\frac{1}{2}\mathbb{R}^n$ and there exists a neighbourhood R of $\psi(p)$ in $\psi[V \cap V'] \subset_{\frac{1}{2}} \mathbb{R}^n$ which does not intersect the boundary of $\frac{1}{2}\mathbb{R}^n$ and which is open in $\frac{1}{2}\mathbb{R}^n$ and also in $\mathbb{R}^n$. Define $U = \psi^{-1}[R]$. U is a neighbourhood of p open in A and a subset of $V \cap V'$. Since $R = \psi[U]$ is open in $\mathbb{R}^n$, $\phi[U]$ is also. U is thus open in B, implying that p lies in the interior $A - \dot{A}$ of A according to the topology of B. Together with the previous result that no point in ∂A lies in $A - \dot{A}$ this implies that $A - \partial A = A - \dot{A}$.∎

From the lemma it follows that any subset $U \subset S$ that is a 3-manifold without boundary ($\partial U = \emptyset$) must coincide with its interior in the topology of $\dot{I}^+[S]$, and thus be open in this topology. This establishes the equivalence of the two definitions of $intS$.

A useful notion of boundary for S is the following:

Definition A.7 *The* embedding boundary *of an achronal subset $S \subset X$ is $\overset{\circ}{S} = \bar{S} - intS$, where $\bar{S}$ is the closure of S in the topology of X.*

$\overset{\circ}{S}$ is simply the topological boundary of S in $\dot{I}^+[S]$. Note that $\overset{\circ}{S}$ does not in general coincide with the causal edge of S defined in [HE73] p.202. It is easy to show that $\overset{\circ}{S} \subset edge[S]$. However not all points of the edge need to lie in $\overset{\circ}{S}$.[74]

[73] A homeomorphism maps the open sets of its domain to open sets in its range. This does not by itself imply that the range is open in the topology of an ambient space whenever the domain is open in an ambient space.

[74] $\overset{\circ}{S}$ does equal $edge[S]$ if strong causality holds. See [HE73] p. 196-197 on Alexandrov topology.

Lemma A.1 provides us with a further useful and obvious corollary.

Proposition A.2 *If Σ is a 3-manifold with boundary achronally embedded in spacetime then int$\Sigma = \Sigma - \partial\Sigma$, the interior of Σ according to its manifold structure, and $\partial\Sigma \subset \overset{\circ}{\Sigma}$.*

Conversely, if the embedding boundary, $\overset{\circ}{S}$, of an achronal set $S \subset X$ is embedded in X then $\bar{S}$ is a manifold with boundary, with $\partial\bar{S} = \overset{\circ}{S}$. [If a manifold is embedded according to our definition (that of [HE73]), which is to say *regularly* embedded in the definition of [CDD82], then according to [CDD82] p. 242 it is a submanifold of the ambient manifold according to the definition of [CDD82] p. 239. The result then follows immediately.] Note that if Σ is closed prop. A.2 implies that $\overset{\circ}{\Sigma} = \partial\Sigma$.

Now we turn to Cauchy surfaces and Cauchy developments.

Definition A.8 *A* Cauchy surface *of an open set $A \subset X$ is an achronal subset C of the closure $\bar{A}$ of A such that any causal curve in A which is inextendible in A crosses C or has an endpoint on C in $\dot{A}$.*

Definition A.9 *An open subset $\mathcal{H} \subset X$ is* globally hyperbolic *in X iff $\mathcal{H}$ contains a Cauchy surface of $\mathcal{H}$.*

Whether $\mathcal{H}$ is globally hyperbolic in X depends to some extent on the properties of the ambient spacetime X. Cauchy surfaces must be achronal, and whether a given subset is achronal depends on the manifold in which it is embedded. However several important consequences of global hyperbolicity hold for a subset $\mathcal{G}$ provided only that it is globally hyperbolic regarded as a manifold by itself, i.e. provided that it's Cauchy surfaces are achronal in $\mathcal{G}$. For instance, this weaker property, which might be called *intrinsic global hyperbolicity*, is sufficient to establish the existence of a foliation of $\mathcal{G}$ by homeomorphic spacelike hypersurfaces [HE73] prop. 6.6.8.

Def. A.9 of global hyperbolicity has been adopted because it is equivalent to the definition used in [HE73]. There a subset $\mathcal{H}$ of X is globally hyperbolic in X iff strong causality holds on the subset[75] and $J^+(p) \cap J^-(q)$ is compact and contained in $\mathcal{H}$ for all $p, q \in \mathcal{H}$. When $\mathcal{H}$ is open this can be shown to be equivalent to the definition A.9 using Geroch's theorem prop. 6.6.8. [HE73] and prop. 6.6.3. of [HE73]. (See [Wald84] p. 209.)

The following result, which extends the relation between Cauchy surfaces and global hyperbolicity established by def. A.9 to Cauchy surfaces outside the globally hyperbolic set, justifies our definition A.8 of Cauchy surfaces.

[75] *Strong causality* holds at p if every neighbourhood of p contains a neighbourhood which causal curves cross at most once. See [HE73].

Proposition A.3 *An open subset $\mathcal{H}$ of X is globally hyperbolic iff $int\bar{\mathcal{H}} = \mathcal{H}$, and $\mathcal{H}$ posses a Cauchy surface.*

Proof: Let $C \subset \bar{\mathcal{H}}$ be a Cauchy surface of $\mathcal{H}$. $\mathcal{H}$ is therefore a subset of $intD[\bar{S}]$ which, by [HE73] Prop 6.6.3, is globally hyperbolic. ($\bar{S}$ is achronal because S is.) Thus strong causality holds at all points of $\mathcal{H}$ and $J^+(p) \cap J^-(q)$ is compact $\forall p, q \in \mathcal{H}$. All that remains to show is that $J^+(p) \cap J^-(q) \subset \mathcal{H}$.

Let $p' \in I^-(p) \cap \mathcal{H}$ and $q' \in I^+(q) \cap \mathcal{H}$, then $J^+(p) \cap J^-(q) \subset I^+(p') \cap I^-(q')$. It is therefore sufficient to show that $I^+(p') \cap I^-(q') \subset \mathcal{H} \ \ \forall p', q' \in \mathcal{H}$.

Suppose this were not so and $I^+(p') \cap I^-(q')$ contains a point r outside $\mathcal{H}$. Let γ be an inextendible timelike curve through p', r, and q'. Since q' and p' lie in $\mathcal{H}$ but r does not, $\gamma \cap \mathcal{H}$ consists of at least two segments that are inextendible in $\mathcal{H}$, one before r, the other after. Each segment must cross C or have an endpoint on C in $\dot{\mathcal{H}}$, so γ crosses C at least once at r or later (according to the parameter of γ), and at least once at r or earlier. On the other hand C is achronal, so γ can in fact cross C only once, implying that the crossing occurs at r, and therefore that $r \in C \subset \bar{\mathcal{H}}$. We may conclude that $I^+(p') \cap I^-(q') \subset \bar{\mathcal{H}}$. But $I^+(p') \cap I^-(q')$ is open, so it must actually be contained in $int\bar{\mathcal{H}} = \mathcal{H}$.

Conversely, if $\mathcal{H}$ is globally hyperbolic it contains a Cauchy surface. What must be shown is that $int\bar{\mathcal{H}} = \mathcal{H}$ in this case. Suppose $p \in int\bar{\mathcal{H}}$, then $\mathcal{H}$ is dense in any sufficiently small open neighbourhood U of p. Let $p' \in I^-(p) \cap U \cap \mathcal{H}$ and $q' \in I^+(q) \cap U \cap \mathcal{H}$, then $p \in I^+(p') \cap I^-(q')$. The argument used to show that $I^+(p') \cap I^-(q') \subset \bar{\mathcal{H}}$ applies, but since the Cauchy surface now is contained in $\mathcal{H}$ one may conclude that $I^+(p') \cap I^-(q') \subset \mathcal{H}$ and thus $p \in \mathcal{H}$. ∎

Prop. A.3 is essentially a generalization of prop. 6.6.3. of [HE73] which states that the interior of the domain of dependence of a closed achronal set is globally hyperbolic. Here we reproduce this very useful result, and also show that the assumption that the achronal set be closed is unnecessary.

Proposition A.4 *The interior of the domain of dependence of any achronal subset of X is globally hyperbolic in X.*

Proof: The claim can be deduced from prop. A.3, but it is easier to prove it directly. Suppose $S \subset X$ is achronal and let $\mathcal{B} = intD[S]$. $\mathcal{B}$ is a subset of $intD[\bar{S}]$ which, by [HE73] Prop 6.6.3, is globally hyperbolic. Thus strong causality holds at all points of $\mathcal{B}$ and $J^+(p) \cap J^-(q)$ is compact $\forall p, q \in \mathcal{B}$. All that remains to show is that $J^+(p) \cap J^-(q) \subset \mathcal{B}$.

Let $p' \in I^-(p) \cap \mathcal{B}$ and $q' \in I^+(q) \cap \mathcal{B}$, then $J^+(p) \cap J^-(q) \subset I^+(p') \cap I^-(q')$. Any point $r \in I^+(p') \cap I^-(q')$ lies between p' and q' on a timelike curve. If this curve is

extended until it is timelike and inextendible then it must cross S, and it must do so precisely once since S is achronal. Any point between p' and the crossing point, or between q' and the crossing point, must lie in $D[S]$ so $r \in D[S]$. Since $I^+(p') \cap I^-(q')$ is open it must in fact be contained in the interior, $\mathcal{B}$, of $D[S]$.∎

A peculiar feature of our definitions is that while the interior of the domain of dependence of an achronal set S is globally hyperbolic S is not necessarily a Cauchy surface of $intD[S]$, because it may not be contained in $\overline{intD[S]}$. For instance suppose σ is a spacelike disk in Minkowski space, and let $S = \dot{I}^-[\sigma]$, $S \cap \overline{intD[S]} = \sigma$. Nevertheless, it will be proved further on (prop. B.11) that $\mathcal{N}$ is a Cauchy surface of $\mathcal{D} \equiv intD[\mathcal{N}]$.

Definition A.10 *The* future Cauchy horizon *of a set S is $H^+[S] = \overline{D[S]} - I^-[D[S]]$*

The past Cauchy horizon is defined analogously.

We may now give the definition of Cauchy developments used in the present work

Definition A.11 *A* smooth Cauchy development *of initial data specified on a 3-manifold Σ is the domain of dependence of Σ embedded achronally in a C^∞,[76] time orientable, Lorentzian metric 4-manifold without boundary such that the data specified on Σ match those induced on Σ by the 4-metric. Moreover the 4-metric is required to satisfy the field equations in the domain of dependence.*

In general Cauchy developments defined in this way are not manifolds (with or without boundary). Nevertheless some work might yield a more intrinsic definition which does not refer to the ambient boundaryless manifold in which the domain of dependence exists. On the other hand we make use of this ambient manifold on occasion, so the definition seems adequate for our purposes.

Given initial data on a given 3-manifold can have many different Cauchy developments. For instance if some of the points in the domain of dependence are eliminated from the ambient manifold the new domain of dependence in the manifold thus reduced would be a proper subset of the original one. More generally for any given Cauchy development there are many others that are isometric to a proper subset. Moreover the Cauchy development might be isometric to a proper subset of a larger one. This leads naturally to the concept of a maximal Cauchy development.

Definition A.12 *A* maximal C^∞ Cauchy development *is a Cauchy development which is not isometric to a proper subset of any other C^∞ Cauchy development of the same data on the same 3-manifold.*

[76] If no hypothesis is made about the degree of differentiability of the 4-metric then it becomes difficult to define what is meant by a solution to the field equations.

Zorns lemma asserts that maximal Cauchy developments exist, while uniqueness theorems assure that they are uniquely determined up to diffeomorphisms by the initial data, for the classes of initial data to which these theorems apply (see [Wald84] p. 263-264).

B Some facts about the null initial data hypersurfaces used in the present work

This appendix collects together results about the topology, geometry, and causal structure of the initial data hypersurface $\mathcal{N}$ (defined in subsection 2.1) and its Cauchy developments.

We shall begin with the local aspects of the geometry of $\mathcal{N}$. It is shown that the tangents of the generators of $\mathcal{N}$ are normal to $\mathcal{N}$. As a consequence all two dimensional cross sections of $\mathcal{N}$ that are transverse to the generators are spacelike and normal to the generators. A converse result is also given that establishes that if the normal vectors of a hypersurface are null, making it a null hypersurface, then these normals are tangent to the hypersurface and integrate to null geodesics that sweep out the hypersurface.

Next we turn to the issue of caustics and crossings of generators. Typically the generators, if extended far enough, will form caustics. But (see fig. 3) a generator may well cross another generator before reaching a caustic and thus enter the chronological future of $\mathcal{N}$. If this occurs $\mathcal{N}$ is not achronal. The question therefore arises whether it is really true that there always exists a solution in which $\mathcal{N}$ with given data is achronal, or whether the initial data must satisfy some additional conditions in order for such a space to exist. Moreover, if there is no such condition, and any data corresponds to an achronal embedding, can a solution in which $\mathcal{N}$ is not achronal be represented by a Cauchy development of initial data?

In a Cauchy development $\mathcal{N}$ is achronal by definition, but we have at present no proof of the existence such developments. There is only a theorem showing the existence of Cauchy developments of a neighbourhood of S_0 in $\mathcal{N}$, and we have been *assuming* that developments of all of $\mathcal{N}$ exist. In the following it will be shown, quite independently of any existence theorem for Cauchy developments, that if $\mathcal{N}$ is not achronal in a spacetime X then there exists a locally isometric covering manifold $\mathcal{V}$ of a neighbourhood of $\mathcal{N}$ in X in which the future directed null geodesics normal to S_0 sweep out an achronal hypersurface covering $\mathcal{N}$. This answers both questions of the previous paragraph: Achronality of $\mathcal{N}$ requires no additional restrictions on the initial data (beyond those that ensure the absence of caustics on $\mathcal{N}$). Furthermore, if we suppose that initial data determines unique maximal Cauchy developments so that (portions of) solution spacetimes can be represented by corresponding initial

data, then solutions in which $\mathcal{N}$ is not achronal are represented by locally isometric covering manifolds with geometry corresponding to the initial data on $\mathcal{N}$. Therefore such solutions *are* represented by initial data, but the identifications that differentiate the covering manifold from the original solution spacetime, and make $\mathcal{N}$ non-achronal, leave no trace in the initial data.

Adopting the covering manifold as our spacetime we can be certain that $\mathcal{N}$ is achronal. Using this we prove a number of further results: Points on $\mathcal{N}$ are causally related iff they lie on the same generator; All Cauchy surfaces of $D[\mathcal{N}]$ share the same boundary $\partial\mathcal{N}$; and others.

Finally two useful results regarding Cauchy developments of $\mathcal{N}$ are established: Firstly, that any Cauchy development of $\mathcal{N}$ may be extended to a boundaryless globally hyperbolic manifold containing $\mathcal{N}$, and secondly, that all Cauchy developments of $\mathcal{N}$, with all possible data, are diffeomorphic to each other (though of course not necessarily isometric).

Let us first revisit the definition of $\mathcal{N}$. Suppose S_0 is smoothly embedded as a spacelike 2-surface in a 4-manifold X with smooth Lorentzian metric and let O be the normal bundle of S_0 (i.e. the bundle of normal vectors). This bundle contains the subbundles $\bar{N}_L$ and $\bar{N}_R$ of future and inward directed null normal vectors and future and outward directed normal null vectors respectively (inward and outward referring to the arbitrarily chosen orientation of S_0). $\mathcal{N}_L$ and $\mathcal{N}_R$ are obtained by suitably truncating each ray of $\bar{N}_L$ and $\bar{N}_R$ and applying the exponential map. Here a *ray* is the set of positive multiples of a vector, and the exponential map is the map that takes a point $p \in X$ and a vector v in the tangent space of X at p to the point of affine parameter 1 on the geodesic with tangent v originating at p. The exponential map is well defined as long as v is not so large that the geodesic leaves X before reaching affine parameter 1, and then it is a smooth map because the metric is smooth (see [HE73] p. 33). Restricted to the normal bundle O it defines a smooth map f from a neighbourhood of S_0 in O into X. The image of the neighbourhood is not open in X but a slight modification of our setup makes it so. Since S_0 is smoothly embedded it may be extended to a (boundary-less) spacelike 2-submanifold $S' \supset S_0$ of X. [The smoothness of the embedding and the Whitney extension theorem [AR67] imply that the embedding map defined on S_0, diffeomorphic to the unit disk in $\mathbb{R}^2$, may be extended to a boundaryless manifold containing S_0. An open subset $S' \supset S_0$ of this extension will be spacelike.] f extends to the normal bundle O' of S' and maps an open neighbourhood of S_0 (or indeed of S') in O' to an open neighbourhood of the same 2-surface in X.

f is not necessarily globally invertible, but if it is restricted to an open subset V of its domain in O' that excludes all points at which the Jacobian df is degenerate, then by the inverse function theorem

Proposition B.1 *$f : V \to X$ is a smooth immersion of V in X. That is, for each point $P \in V$ there is a neighbourhood U of P such that f restricted U is a smooth diffeomorphism of U to $f[U]$.*

Note that the images in X of points in O at which *df is* degenerate are caustics of the congruence of geodesics normal to S_0. That is, they are points at which neighbouring normal geodesics cross, or nearly cross in the sense that the coordinate separation of points of equal affine parameter on a family of nearby normal geodesics is zero to first order in the difference between their initial data - in the differences between the coordinates of their starting points on S_0 and of the components of their initial tangents.

The truncations, N_L and N_R, of $\bar{N}_L$ and $\bar{N}_R$ which, when exponentiated, give rise to $\mathcal{N}_L$ and $\mathcal{N}_R$ are chosen so that there are no caustics on $\mathcal{N}_L$ or $\mathcal{N}_R$. V may thus be chosen to so that it contains N_L and N_R. V will furthermore be chosen so that any ray of O' leaves V at most once. It is then simply connected. prop. B.1 implies that V is a covering manifold of $f[V] \subset X$. Let us denote by $\mathcal{V}$ the manifold V equipped with the metric pulled back from X via f. $\mathcal{V}$ is then a locally isometric covering manifold of $f[V]$. The exponential map $\hat{f} : V \to \mathcal{V}$ of V into $\mathcal{V}$ is simply the identity map from V to $\mathcal{V}$ and thus evidently one to one.

In the following we will mostly study the hypersurface $\mathcal{N} = \hat{f}[N_L \cup N_R]$ swept out by the future directed null geodesics normal to S_0 in the covering spacetime $\mathcal{V}$. Since this $\mathcal{N}$ maps to the old $\mathcal{N}$ in X when the isometric identifications are made that reduce $\mathcal{V}$ to $f[V] \subset X$, any local property of $\mathcal{N}$ in $\mathcal{V}$ is shared by $\mathcal{N}$ in X. In the corresponding Cauchy problem data is given on $N = N_L \cup N_R$ and the embedding of N in the Cauchy development is diffeomorphic to $\mathcal{N}$ in $\mathcal{V}$.

Note that in our original definition of $\mathcal{N}$ we only required that the generators of $\mathcal{N}$ not form any caustics on $\mathcal{N}$. Here we require that the congruence of geodesics normal to S_0, which includes also timelike and spacelike geodesics, not form caustics on $\mathcal{N}$. In prop. B.4 the two conditions will be shown to be equivalent.

Now let us establish the key local property of $\mathcal{N}$, namely that it is a null hypersurface and the null normal vectors are the tangents to the generators:

Proposition B.2 *The tangents to the generators of a branch $\mathcal{N}_A$ of $\mathcal{N}$ are normal to $\mathcal{N}_A$.*

Proof: Suppose ζ is a tangent vector of $\mathcal{N}_A$ at a point p. Let λ be an affine parametrization of the generators of $\mathcal{N}_A$ such that the corresponding field of tangent vectors $l \equiv d/d\lambda$ of these is smooth (this requires only that $d/d\lambda$ be chosen smooth on S_0), and define the vector field η on the generator through p by Lie dragging ζ along the generator. That is, define η to be the field of vectors tangent to $\mathcal{N}_A$ that satisfies the differential equation $\pounds_l \eta = 0$ and the initial condition $\eta(p) = \zeta$.

Since η is tangent to $\mathcal{N}_A$ at S_0 it can have only components tangent to S_0 and to l. This implies that $l \cdot \eta = 0$ there, for the component tangent to S_0 is orthogonal to l by the definition of the generators, and the component tangent to l is orthogonal to l since l is null. But $l \cdot \eta$ is constant along the generator through p: $\pounds_l \eta = 0$ means that $\nabla_l \eta = \nabla_\eta l$, and, since l is the tangent to an affinely parametrized geodesic, $\nabla_l l = 0$, so

$$\frac{d}{d\lambda}[l \cdot \eta] = l \cdot \nabla_l \eta = l \cdot \nabla_\eta l = \frac{1}{2}\frac{d}{d\lambda} l^2 = 0. \tag{342}$$

Thus $l \cdot \eta = 0$ at p.∎

A converse result is worth noting.

Proposition B.3 *On an arbitrary null hypersurface $\mathcal{K}$ (a hypersurface with null normal everywhere) in a smooth Lorentzian metric manifold Y the normals are tangent to the hypersurface and*

integrate to a congruence of null geodesic curves that sweep out the hypersurface.

Proof: Let w be a function on Y that is constant on $\mathcal{K}$ and has non-zero gradient there. Then $k = \vec{dw}$, obtained by acting with the inverse metric on dw, is a normal vector field on $\mathcal{K}$, which by assumption is null and thus has null integral curves. The torsion freeness of the connection implies that these integral curves are geodesics:

$$0 = 2k^\mu \nabla_{[\mu} \nabla_{\nu]} w = \nabla_k k_\nu - k^\mu \nabla_\nu k_\mu = \nabla_k k_\nu - \frac{1}{2}\nabla_\nu k^2, \tag{343}$$

so $\nabla_k k \propto k$, since $k^2 = 0$ on $\mathcal{K}$. That is, k is parallel transported, modulo modulus, along it's integral curves which are therefore geodesics.∎

Note that *any* 2-surface $\sigma \subset \mathcal{K}$ that cuts the integral curves of the normals is of course orthogonal to these. (This means that in any local Lorentz frame in which an element of σ is purely spatial the integral curve emerging from this element is spatially normal to it.)

Note also that if the level sets of w are null hypersurfaces in a neighbourhood of $\mathcal{K}$, or indeed if only the gradient of $(dw)^2 \equiv k^2$ vanishes on $\mathcal{K}$, then it follows from (343) that the integral curves of k are affinely parametrized geodesics.

We are now ready to show that the restrictions we place on the initial data imply that df is non-degenerate on N, which is to say, the generators of $\mathcal{N}$ and neighbouring geodesics normal to S_0 form no caustics on $\mathcal{N}$. What are these restrictions? Suppose γ is a generator of a branch $\mathcal{N}_A$ of $\mathcal{N}$, and thus the image of a ray of N, and suppose P is a point on this ray. Then the area parameter at P is defined to be $r(P) = \sqrt{A(P)/\bar{A}}$, the root of the cross sectional area A at $f(P)$ of an infinitesimal bundle of generators

neighbouring γ, over the cross sectional area $\bar{A}$ of the same bundle at the truncating surface S_A. (See subsection 3.1). In the initial data sets we admit the area parameter along each ray starts at a finite, positive, non-zero value r_0 at the beginning of the ray on S_0 and increases or decreases monotonically to a value of 1 at the truncating surface where the ray leaves N. Thus a bundle of generators having non-zero cross sectional area on S_0 necessarily has non-zero cross sectional area everywhere along its trajectory to S_A.

This restriction on the initial data together with the following proposition implies that *df* is non-degenerate on N.

Proposition B.4 *df is non-degenerate on N provided r/r_0 does not vanish on $\mathcal{N}$.*

Proof: If *df* is degenerate at a point $P \in O$ then f maps any basis of the space T_P of vectors tangent to O at P to a linearly *dependent* set of tangent vectors to X at $p = f(P) \in X$. To show that *df* is non-degenerate on a branch N_A of N we will choose a basis of T_P for all $P \in N_A$ and show that the 4-volume spanned by the image of this basis is non-zero, implying that the four image vectors are linearly independent.

Coordinates can be defined on N_A as follows: Choose coordinates on S_0 and convect these along the rays to all of N_A (i.e. set them to be constant on the rays), then choose a linear parameter λ on each ray so that $\lambda = 0$ on S_0 and the $\lambda = 1$ surface is smooth. The associated coordinate basis consists of $L = d/d\lambda$, tangent to the null rays of N_A, and two vectors, E_1 and E_2, corresponding to the coordinates on S_0. This can be completed to a basis of tangents to O on N_A by including a timelike vector T which is tangent to the fibres of O and constant in each fibre. (T is timelike according to the metric on the tangent space of X at the base of the fibre on S_0 where T can be regarded to reside since it is constant on the fibre). At each point $P \in N_A$ f pushes these vectors forward to vectors l, e_1, e_2, and τ tangent to X at $p = f(P)$. l is tangent to the generator through p and thus null and normal to $\mathcal{N}_A$, while e_1 and e_2 are tangent to $\mathcal{N}_A$ and thus normal to l. Since $0 = l \cdot l = l \cdot e_1 = l \cdot e_2$ the 4×4 matrix of inner products of these vectors[77] falls into a block diagonal form and the 4-volume spanned by them is easily seen to be $-l \cdot \tau A$, where A is the area spanned by e_1 and e_2.

Since L and T are non-zero null and timelike vectors respectively the inner product $l \cdot \tau$ is necessarily non-zero at S_0. Less obviously, this inner product is constant along each generator: The displacement from a point on a ray of N_A, generated by L, to the

[77] When l, e_1, e_2, and τ are linearly independent, and thus form a basis, the matrix of their inner products is the matrix of covariant components of the metric referred to this basis. The matrix of inner products is of course defined even when these vectors are not linearly independent. The 4-volume is given by the square root of minus the determinant of the matrix of inner products in either case.

corresponding point on the timelike ray of O generated by the vector $L+T$ is given by the vector field $V(\lambda) = \lambda T$ on the null ray. $\lambda\tau$ is thus a geodesic deviation vector field, or Jacobi field, and it is subject to the geodesic deviation equation: $\nabla_l \nabla_l \lambda\tau^\mu = \lambda R^\mu_{\tau ll}$. Since $\nabla_l l = 0$ the inner product $\lambda l \cdot \tau$ satisfies

$$\frac{d^2}{d\lambda^2}\lambda[l \cdot \tau] = l \cdot \nabla_l \nabla_l \lambda\tau = \lambda R_{\tau lll} = 0, \tag{344}$$

which shows that $\lambda l \cdot \tau$ is linear in λ, and hence that $l \cdot \tau$ is constant along the generator. In conclusion $l \cdot \tau$ is non-zero everywhere on the generator.

Degeneracy of df on N_A would therefore require that the area A spanned by e_1 and e_2 vanish somewhere on a generator. But $A = A_0(r/r_0)^2$, where A_0 is the area spanned by these vectors at S_0, which is non-zero by definition. The condition that r/r_0 not vanish thus guarantees that A does not vanish and df is non-degenerate.∎

Now let us show that $\mathcal{N}$ is achronal in $\mathcal{V}$. This of course does depend on the fact that $\mathcal{N}$ is embedded, and not merely immersed, in $\mathcal{V}$. The square $s = v \cdot v$ (according to the metric on S') of the vectors orthogonal to S' constitutes a smooth function on O', and thus on $\mathcal{V}$. At a point $p \in \mathcal{V}$ s is minus the proper time squared elapsed along the orthogonal geodesic segment γ_p from S' to p, or, if γ_p is spacelike, it is the length squared of γ_p.

s is also the value on these geodesic segments of the action functional $\sigma[c] = \int_0^1 v \cdot v \, dt$, when t is an affine parameter. This action functional is defined for an arbitrary differentiable curve $c : [0,1] \to \mathcal{V}$, with t the parameter of the curve and $v = d/dt$ the corresponding tangent vector. When the curve is the geodesic segment γ_p normal to S' parametrized affinely so that $c(1) = p$ then, firstly, $v(0)$ is the vector at $c(0) \in S'$ that the exponential map associates to p, and, secondly, v is parallel propagated so $v \cdot v$ is constant on the geodesic. As a consequence $\sigma = s$.

Using this correspondence we may prove the following useful lemma:

Lemma B.5 *The level set of s passing through p is orthogonal to γ_p. Indeed the gradient vector $\vec{ds}$ of s (obtained by acting with the inverse metric on ds) is tangent to γ_p and points away from S'.*

Proof: A direct calculation shows that under a variation of c

$$\delta\sigma = 2\,[\delta c \cdot v]_0^1 - 2\int_0^1 \delta c \cdot \nabla_v v \, dt. \tag{345}$$

(δc is the vector field on the curve generating its displacement). This allows us to evaluate the gradient of s. Let us restrict attention to the geodesic segments γ_p and vary p. The base point of γ_p on S' varies, but according to (345), since $v(0)$ is

orthogonal to S' this variation makes no contribution to the variation of σ. Since γ_p is a geodesic there is no contribution from the integral term either. The variation of the action thus is $\delta\sigma = 2\delta c(1) \cdot v(1)$

$$\vec{ds} = 2v(1). \tag{346}$$

From this the claim follows immediately.∎

Now let us use this lemma. Let V^+ be the subset of V consisting of future directed causal vectors. It follows from lemma B.5 that s is strictly decreasing along any future directed timelike curve in $\mathcal{V}^+ \equiv \hat{f}[V^+]$. From this we see immediately that

Proposition B.6 *$\mathcal{N}$ is achronal in $\mathcal{V}$.*

Proof: If $\mathcal{N}$ were not achronal then there would exist a future directed timelike curve in $\mathcal{V}$ crossing $\mathcal{N}$ twice. Moreover, by [Wald84] theorem 8.1.2., this curve may be chosen to be piecewise geodesic, and thus piecewise differentiable. [An arbitrary timelike curve may be covered with a sequence of convex normal neighbourhoods so that successive neighbourhoods overlap. Then a sequence of points may be chosen lying on the curve and in the overlaps of successive neighbourhoods and successive points in *this* sequence may be connected by timelike geodesics, which always exist by the theorem.] s is strictly decreasing along the curve at any point in $\mathcal{V}^+ - S_0$. The curve starts on $\mathcal{N} \subset \mathcal{V}^+$ where $s = 0$, and if it starts on S_0 it immediately enters $\mathcal{V}^+ - S_0$ because it is timelike and future directed. Since the curve can leave $\mathcal{V}^+ - S_0$ only if s returns to 0, its value on the boundary of this set, the curve can in fact not leave $\mathcal{V}^+ - S_0$ and s always continues to decrease strictly after the starting point of the curve. An endpoint of the curve on $\mathcal{N}$ would therefore have $s < 0$, but $s = 0$ on all of $\mathcal{N}$. ∎

Prop. B.6 establishes that the achronality of $\mathcal{N}$ requires no restrictions on the initial data, save that it make $\mathcal{N}$ caustic free. The absence of caustics implies that $\mathcal{N}$ can always be made achronal by going to the covering manifold $\mathcal{V}$ of a neighbourhood of $\mathcal{N}$.

$\mathcal{V}$ does not necessarily cover all of the domain of dependence of $\mathcal{N}$, even in ambient spacetimes in which $\mathcal{N}$ is achronal. A caustic in the timelike geodesics normal to S_0 might well form inside $D[\mathcal{N}]$ without there being any sort of pathology in $D[\mathcal{N}]$ that one would wish to exclude. Thus $\mathcal{V}$ is not in general large enough to be the ambient spacetime of the maximal Cauchy developments of data on $\mathcal{N}$. Nevertheless, the domain of dependence of $\mathcal{N}$ in $\mathcal{V}$, while not the *maximal* Cauchy development is sufficient for our purpose of defining a pre-Poisson bracket on the initial data. One may define the observables on these, non-maximal, Cauchy developments, and

the Peierls bracket on these determines an almost unique pre-Poisson bracket on the initial data.

For the sake of completeness, and conceptual simplicity, I define further on a boundaryless manifold M which contains both $\mathcal{N}$ as an achronal submanifold and the interior of the maximal Cauchy development of the data on $\mathcal{N}$. This construction is not necessary to justify the main results of the present work.

We are now in a position to show that

Proposition B.7 *In $\mathcal{V}$ the subset of $\mathcal{N}$ that is causally connected to a point $p \in \mathcal{N}$ (i.e. lies in $J^+[p] \cup J^-[p]$) consists of the points on the generators through p.*

Proof: Suppose q and r are points of $\mathcal{N}$ that are causally connected, with q to the future of r: $q \in J^+(r)$. Let $\mathcal{N}_e$ be the extension of $\mathcal{N}$ swept out by the generators of $\mathcal{N}$ continued to the future as null geodesics until they leave $\mathcal{V}$. $s = 0$ on $\mathcal{N}_e$ so $\mathcal{N}_e$ is achronal in $\mathcal{V}$ by the same argument used to prove the achronality of $\mathcal{N}$ (prop. B.6). Now suppose q' lies on the generator through q to the future of q, then a causal curve γ from r to q followed by the generator segment from q to q' defines a causal curve from r to q' which may be deformed to a timelike one unless it is a null geodesic. The achronality of $\mathcal{N}_e$ thus implies that γ is a null geodesic that continues the generator segment from q to q' to the past, that is, it implies that γ coincides with the generator through q and q'. It follows that r and q necessarily lie on the same generator. ∎

A further property of $\mathcal{N}$ that we will use is

Proposition B.8 *If W is a neighbourhood of $\partial\mathcal{N}$ in $\mathcal{N}$ then there exists a neighbourhood U of the boundary in S_0 such that all generators of $\mathcal{N}$ incident on U lie entirely in W.*

Proof: Consider one branch $\mathcal{N}_A$ of $\mathcal{N}$. The complement C of W in $\mathcal{N}_A$ is a closed subset of $\mathcal{N}_A$, and $\mathcal{N}_A$ is compact. Thus C is compact. The map $\pi : \mathcal{N}_A \to S_0$ which takes the points on a generator to the origin of that generator on S_0 is continuous - it is just the composition of the diffeomorphism $\hat{f}^{-1}$ (restricted to $\mathcal{N}_A$) with the projection to the base manifold in O. Thus $\pi[C]$ is compact and therefore closed. It follows that the complement U_A of $\pi[C]$ is open. Since C does not intersect $\partial\mathcal{N}$ and $\pi^{-1}[\partial S_0] \subset \partial\mathcal{N}$, $\pi[C]$ does not intersect ∂S_0. Thus U_A is an open neighbourhood of ∂S_0. The same is of course true of $U = U_R \cap U_L$.∎

Now we turn to properties of Cauchy developments of $\mathcal{N}$. We begin with a pair of lemmas about achronal sets.

Lemma B.9 *If S is an achronal set then its embedding boundary $\overset{\circ}{S}$ lies outside the domain of influence $I[D[S]]$ of the domain of dependence of S.*

Proof: Since $\dot{I}^+[S]$ is achronal (by [HE73] prop. 6.3.1.) a timelike curve can cross $\dot{I}^+[S]$ at most once. On the other hand all inextendible timelike curves through $D[S]$ must cross $S \subset \dot{I}^+[S]$. They can thus not cross $\dot{I}^+[S]$ outside S as well. Indeed no timelike curve through $D[S]$ can cross $\dot{I}^+[S] - S$ since any such curve could be extended until inextendible. $I[D[S]] \cap \dot{I}^+[S]$ is thus a subset of S, and since it is open in the topology of $\dot{I}^+[S]$ it must be contained in the interior of S and be disjoint from $\overset{\circ}{S}$.∎

Lemma B.10 *Suppose S is an achronal set and $p \in intS$, then $I^+(p) \cap D[S] = \emptyset$ iff there exists a null geodesic in S passing through p without past endpoint in the interior of S.*

Proof: If there exists a null geodesic segment γ in S passing through p without past endpoint in $intS$ then either this segment is past inextendible in spacetime or it has a past endpoint s in the closure $\bar{S}$ of S, and thus in $\overline{S} - intS = \overset{\circ}{S}$. In the first case there exists (by [Wald84] lemma 8.1.4.) through any $q \in I^+(p)$ a past inextendible timelike curve contained in $I^+[\gamma] \subset I^+[S]$. Since S is achronal this curve never crosses S, implying that $q \notin D[S]$. In the second case one may remove the end point s from the spacetime making γ past inextendible. In the spacetime without s there again exists a past inextendible timelike curve through q contained in $I^+[S]$. This curve is either inextendible in the full spacetime, indicating that $q \notin D[S]$, or $s \in \dot{S}$ is its past endpoint. But by lemma B.9 no timelike curve through $D[S]$ passes through $\overset{\circ}{S}$, so also in this case $q \notin D[S]$. $I^+(p)$ is thus disjoint from $D[S]$.

Now to the converse: if $I^+(p)$ is disjoint from $D[S]$ then there exists a sequence of points q_i in $I^+(p)$ approaching p and causal, past inextendible curves γ_i through the q_i which do not intersect S. The portions, γ_i', of these curves that lie in $I^+[S]$ are either past inextendible or have past endpoints on $\dot{I}^+[S] - S$. Removing the closed set $\dot{I}^+[S] - intS$ from spacetime leaves a manifold in which the γ_i' are all past inextendible. By lemma 6.2.1. of [HE73] there must exist a causal, past inextendible limit curve of the γ_i' through p. Since the γ_i' all lie in the closed set $\bar{I}^+[S]$ the limit curve does so also. But, because S is achronal the limit curve cannot enter $I^+[S]$. It is thus confined to $\bar{I}^+[S] - I^+[S] = \dot{I}^+[S]$, which is just $intS$ in this manifold. Moreover the limit curve, which is causal, must be a null geodesic, for if it were not then two points on the curve could be connected by a timelike curve, violating the achronality of S. ∎

Note that when $I^+(p) \cap D[S]$ is non empty for some $p \in S$ then in fact all of $I^+(p)$ that lies within a neighbourhood U of p is contained in $D[S]$: If $r \in I^+(p) \cap D[S]$ then we may take $U = I^-(r)$, because $p \in I^-(r)$ and past directed timelike curves from r that have not yet reached S must be contained in $D[S]$, so $I^-(r) \cap I^+(p) \subset D[S]$.

Lemma B.10 allows one to demonstrate some intuitively plausible basic facts about the domain of dependence of $\mathcal{N}$.

Proposition B.11 *For all $p \in int\mathcal{N}$, the part of $I^+(p)$ lying in a sufficiently small neighbourhood of p is contained in $D[\mathcal{N}]$ while $\overline{I^-(p)}$ does not intersect $D[\mathcal{N}]$. Thus $D[\mathcal{N}] = D^+[\mathcal{N}]$, $intD[\mathcal{N}]$ is non empty, $\mathcal{N} \subset \overline{intD[\mathcal{N}]}$, and $\mathcal{N}$ is a Cauchy surface of $intD[\mathcal{N}]$.*

Proof: By prop. B.7 the only null geodesics in $\mathcal{N}$ passing through a point $p \in int\mathcal{N}$ are the generators through p. These have past endpoints on $intS_0 \subset int\mathcal{N}$, and future endpoints on S_L or S_R, both subsets of $\partial\mathcal{N} \subset \overset{\circ}{\mathcal{N}}$. Thus by lemma B.10 $I^+(p)$ must intersect $D[\mathcal{N}]$, while $I^-(p)$ must not intersect $D[\mathcal{N}]$. That $U \cap I^+(p) \subset D[\mathcal{N}]$ for some neighbourhood U of p follows from the remarks after the proof of that lemma. $D[\mathcal{N}] = D^+[\mathcal{N}]$, $intD[\mathcal{N}] \neq \emptyset$, and $\mathcal{N} \subset \overline{intD[\mathcal{N}]}$ follow immediately. $\mathcal{N} \subset \overline{intD[\mathcal{N}]}$ implies that $\mathcal{N}$ is a Cauchy surface of $intD[\mathcal{N}]$ according to def. A.8.∎

Since the interior of the domain of dependence of the initial data hypersurface $\mathcal{N}$ we are using does not cover the whole spacetime, and in fact does not even include $\mathcal{N}$ itself, it has been necessary to adopt a wider notion of Cauchy surfaces than is usual (see def. A.8). In the following we shall see that despite this more ample definition, the Cauchy surfaces $intD[\mathcal{N}]$ are quite simple: They are all embedded manifolds homeomorphic to $\mathcal{N}$ with boundary coinciding with $\partial\mathcal{N}$.

Proposition B.12 *If C and C' are both Cauchy surfaces of an open set $\mathcal{H} \subset X$, then $\overset{\circ}{C}=\overset{\circ}{C'}$.*

Proof: $\overset{\circ}{C}$ is the boundary of $\bar{C}$ in $\dot{I}^+[C]$ and also of its complement in $\dot{I}^+[C]$: $\overset{\circ}{C}= [\dot{I}^+[C] - \bar{C}]^\circ$. But

$$\dot{I}^+[C] - \bar{C} = \dot{I}^+[\mathcal{H}] - \bar{\mathcal{H}}, \tag{347}$$

the left side being a set depending only on $\mathcal{H}$ and not on the choice of Cauchy surface. To justify (347) note that $I^+[C] \subset I^+[\bar{\mathcal{H}}] = I^+[\mathcal{H}]$, and conversely $I^+[\mathcal{H}] - \bar{\mathcal{H}} \subset I^+[C] - \bar{\mathcal{H}}$, for if $p \in I^+[\mathcal{H}] - \bar{\mathcal{H}}$ then there exists a timelike curve from a point $q \in \mathcal{H} \cap I^-(p)$ to p which, when extended to an inextendible timelike curve necessarily crosses C, and does so to the past of p since any point on the curve between q and the crossing point lies in $\bar{\mathcal{H}}$. It follows that

$$I^+[C] - \bar{\mathcal{H}} = I^+[\mathcal{H}] - \bar{\mathcal{H}}. \tag{348}$$

Now

$$\dot{I}^+[\mathcal{H}] - \bar{\mathcal{H}} = [I^+[\mathcal{H}] - \mathcal{H}]^\cdot - \bar{\mathcal{H}} = [I^+[C] - \mathcal{H}]^\cdot - \bar{\mathcal{H}} = \dot{I}^+[C] - \bar{\mathcal{H}}. \tag{349}$$

In the rightmost expression $\bar{\mathcal{H}}$ may be replaced by $\bar{C}$: $\bar{\mathcal{H}} \subset \overline{D[\bar{C}]}$, hence, by [HE73] prop. 6.5.1, for any point $r \in \bar{\mathcal{H}}$ there is a timelike curve passing through both r and a point $s \in \bar{C}$. Since $\dot{I}^+[C]$ is achronal the curve can intersect $\dot{I}^+[C] \supset \bar{C}$ *only* at the one point s, so if $r \in \dot{I}^+[C]$ as well as $\bar{\mathcal{H}}$ then $r = s \in \bar{C}$. This establishes (347), and also the claim of the proposition. ∎

Since $\mathcal{N}$ is compact, and thus closed in spacetime, $\overset{\circ}{\mathcal{N}} = \partial\mathcal{N}$, so prop. B.12 implies that for any Cauchy surface C of $intD[\mathcal{N}]$ $\overset{\circ}{C} = \partial\mathcal{N}$. Indeed, we shall see that $\bar{C}$ is a manifold with boundary that is homeomorphic to $\mathcal{N}$. It follows that $\partial\bar{C} = \overset{\circ}{C} = \partial\mathcal{N}$.

To demonstrate homeomorphism we first establish a lemma:

Let us define the *minimal component*, C^0, of a Cauchy surface C of an open hyperbolic set $\mathcal{H}$, to be $C \cap I[\mathcal{H}]$.[78]

Proposition B.13 *If C is a Cauchy surface of an open set $\mathcal{H}$ then $\overline{C} - C^0 = \overline{\mathcal{H}} - I[\mathcal{H}]$.*

Proof: It is evident that $\overline{C} - C^0 \subset \overline{\mathcal{H}} - I[\mathcal{H}]$. What must be shown is thus that *all* points of $\overline{\mathcal{H}} - I[\mathcal{H}]$ lie in $\overline{C} - C^0$. Since $C^0 \subset I[\mathcal{H}]$ it is sufficient to show that $\overline{\mathcal{H}} - I[\mathcal{H}] \subset \overline{C}$. The achronality of C implies that $\overline{C}$ is also achronal. Therefore, since C is a Cauchy surface for $\mathcal{H}$, $\overline{C}$ is as well. As a consequence $\mathcal{H} \subset D[\overline{C}]$ implying that $\overline{\mathcal{H}} \subset \overline{D[\overline{C}]}$. By [HE73] prop. 6.5.1, this implies that all inextendible timelike curves through $\overline{\mathcal{H}}$ must pass through $\overline{C}$. But if $p \in \overline{\mathcal{H}} - I[\mathcal{H}]$ then $I(p)$ is disjoint from $\mathcal{H}$, and indeed from $\overline{\mathcal{H}} \supset \overline{C}$, since $I(p)$ is open. The only point on a timelike curve through p not in $I(p)$ is p itself, so this is the only point at which the curve can intersect $\overline{C}$: $p \in \overline{C}$. ∎

Proposition B.14 *If C and C' are both Cauchy surfaces of the open set $\mathcal{H} \subset X$, then $\bar{C}$ is homeomorphic to $\bar{C}'$.*

Proof: Let v be a smooth vector field on X. (By lemma 8.1.1 of [Wald84] such a field always exists on a paracompact, time orientable, smooth, Lorentzian metric manifold. See also [HE73] pp. 38-40.) Each integral curve of v is inextendible in X, so if it passes through $\mathcal{H}$ it must cross both C and C' exactly once. The integral curves thus

[78] C^0 is the only part of C which causal curves through $\mathcal{H}$ actually cross. (Because $\mathcal{H}$ is open $J[\mathcal{H}] = I[\mathcal{H}]$). Thus C^0 is precisely that part of C that is necessary for it to function as a Cauchy surface for $\mathcal{H}$. A Cauchy surface of $\mathcal{H}$ contained in $\mathcal{H}$ is equal to its minimal component. On the other hand $\partial\mathcal{N}$ is not part of the minimal component of $\mathcal{N}$. Indeed lemmas B.9 and B.10 (and the time reverse of lemma B.10) indicate that for any Cauchy surface C^0 consists of C minus its boundary and any null geodesics without future or past endpoint in $intC$. In particular, by prop. B.11 and lemma B.9 $\mathcal{N}^0 = int\mathcal{N}$.

establish a 1-1 correspondence between $C^0 \equiv C \cap I[\mathcal{H}]$ and $C'^0 \equiv C' \cap I[\mathcal{H}]$. By prop. B.13 $\bar{C} - C^0 = \bar{\mathcal{H}} - I[\mathcal{H}] = \bar{C}' - C'^0$ so this 1-1 correspondence actually extends to a 1-1 correspondence between $\bar{C}$ and $\bar{C}'$. Moreover, this correspondence is continuous and has continuous inverse: The smoothness of v implies that the points on the integral curves are continuous functions of the curve parameter and of the starting point of the curve. Furthermore the achronality of C and C' imposes a Lipschitz condition on the curve parameter value of the point $p' \in C'$ that corresponds to a point $p \in C$, implying that this parameter is a continuous function on C. p' is thus a continuous function of p. Reversing the roles of C and C' one sees that the inverse is also continuous ∎

The preceding results together establish that

Proposition B.15 *The closure of any Cauchy surface of $\mathcal{D} = intD[\mathcal{N}]$ is an embedded compact 3-manifold with boundary $\partial\mathcal{N}$ that is homeomorphic to $\mathcal{N}$, and thus to the closed unit cube in $\mathbb{R}^3$.*

In an open globally hyperbolic region the wave equation, and similar equations, such as the linearized Einstein field equation in transverse gauge (13), have unique advanced and retarded Green's function (see [CDD82] p. 523). It is therefore relevant when using Green's functions in conjunction with initial data on $\mathcal{N}$, as we do, that

Proposition B.16 *$\mathcal{N}$ is contained in an open subset $\hat{\mathcal{V}}$ of $\mathcal{V}$ which, when regarded as a spacetime in its own right, is globally hyperbolic.*

The proof consists in extending $\mathcal{N}$ to a larger achronal hypersurface Λ and showing that $\mathcal{N} \subset intD[\Lambda] \equiv \hat{\mathcal{V}}$. In fact it will not be shown that Λ is achronal in $\mathcal{V}$, but rather in an open subset $\mathcal{V}'$, which will serve as the spacetime in which $D[\Lambda]$ is defined

Proof part I. Definition of $\mathcal{V}'$ and Λ: $\mathcal{V}'$ is an open subset of $\mathcal{V}$ containing $\mathcal{N}$, that is, like $\mathcal{V}$, an exponential of an open subset (V') of O' from which any ray of O' exits at most once. $\mathcal{V}'$ thus has all the properties that have been demanded of $\mathcal{V}$, and could be taken in place of $\mathcal{V}$ in all preceding theorems. In addition the closure of $\mathcal{V}'$ in $\mathcal{V}$ will be required to be compact. [This requirement is easily fulfilled. For instance, define a Riemannian metric on O', and let $\mathcal{V}'$ be a subset of the cylinder formed by vectors in O' that are shorter than twice the maximal length of the vectors in the compact subset N.] As a consequence any geodesic normal to S' crosses the boundary of $\mathcal{V}'$ before leaving $\mathcal{V}$.

The construction of Λ proceeds in two steps. The first step is to extend $\mathcal{N}$ to a hypersurface $\tilde{\mathcal{N}}$ just like $\mathcal{N}$ but slightly larger. Like $\mathcal{N}$, $\tilde{\mathcal{N}}$ is swept out by future directed null geodesic generators normal to a compact spacelike 2-disk that are truncated before reaching a caustic. The 2-disk $\tilde{S}_0$ on which the generators of $\tilde{\mathcal{N}}$ originate

contains S_0 in its interior, and the surfaces $\tilde{S}_L$ and $\tilde{S}_R$ on which the generators are truncated are chosen to lie beyond S_L and S_R, so that $\mathcal{N} \subset int\tilde{\mathcal{N}}$. Recall that O' is the normal bundle of a smoothly embedded, boundaryless, spacelike 2-manifold $S' \supset S$ (which is defined before prop. B.1). $\tilde{S}_0$ will be taken to be a compact disk with smooth boundary in S' that contains S_0 in its interior. Furthermore $\tilde{S}_L$ and $\tilde{S}_R$ will be chosen close enough to $\mathcal{N}$ so that they (and thus all of $\tilde{\mathcal{N}}$) lie within $\mathcal{V}'$. Thus $\tilde{\mathcal{N}} = \hat{f}[\tilde{N}]$ where $\tilde{N} \supset N$ is a subset of V', and prop. B.6 implies that $\tilde{\mathcal{N}}$ is achronal.

Having defined $\tilde{\mathcal{N}}$ we now define Λ to be $\dot{I}^-[\tilde{\mathcal{N}}]$. This is an achronal embedded 3-manifold, by [HE73] prop. 6.3.1.

To show that $\mathcal{N} \subset intD[\Lambda]$ we use the following lemma:

Lemma B.17 *Suppose λ' is the maximal extension (as a null geodesic) of a generator of $\tilde{\mathcal{N}}$ in the spacetime $\mathcal{V}'$, then $\lambda' \cap \overline{I^-[\tilde{\mathcal{N}}]} \subset \tilde{\mathcal{N}}$ in this spacetime.*

Proof: Suppose $p \in \lambda' \cap \overline{I^-[\tilde{\mathcal{N}}]} - \tilde{\mathcal{N}}$. Then there exists a sequence of points $\{p_n\}$ in $I^-[\tilde{\mathcal{N}}]$ in $\mathcal{V}'$ approaching p, and for each p_n a future directed timelike curve γ_n in $\mathcal{V}'$ from p_n to $\tilde{\mathcal{N}}$. Now consider the problem in the context of the larger ambient spacetime $\mathcal{V} \supset \mathcal{V}'$. The γ_n are timelike curves in $\mathcal{V}$ that are inextendible in $\mathcal{V} - \tilde{\mathcal{N}}$ so, by [HE73] lemma 6.2.1, they have a causal limit curve γ through p which is also inextendible in $\mathcal{V} - \tilde{\mathcal{N}}$, and thus either inextendible in $\mathcal{V}$ or has an endpoint on $\tilde{\mathcal{N}}$.

Now note that the proof of prop. B.6 applies equally well to $\tilde{\mathcal{N}}$ in $\mathcal{V}$ and shows that it is achronal in $\mathcal{V}$. This implies that γ coincides with λ, the maximal extension as a null geodesic of λ' in $\mathcal{V}$, to the future of p: γ lies in $\overline{I^-[\tilde{\mathcal{N}}]}$ and thus, since $\tilde{\mathcal{N}}$ is achronal, outside $I^+[\tilde{\mathcal{N}}]$. But following λ from a point on $\tilde{\mathcal{N}}$ to p and then continuing along γ one obtains a causal curve that may be deformed to a timelike one, which would imply that γ enters $I^+[\tilde{\mathcal{N}}]$, unless γ coincides with λ after p. On the other hand the γ_n are all contained in $\mathcal{V}'$, and hence γ is contained in the compact set $\overline{\mathcal{V}'}$. γ must thus have an endpoint at $\lambda \cap \dot{\mathcal{V}}'$ which does not lie on $\tilde{\mathcal{N}}$, contained in the open set $\mathcal{V}'$. A contradiction has been reached, implying that $\lambda' \cap \overline{I^-[\tilde{\mathcal{N}}]} - \tilde{\mathcal{N}}$ is in fact empty in $\mathcal{V}'$. ∎

proof of prop. B.16 part II: Suppose $p \in \mathcal{N} \subset int\tilde{\mathcal{N}}$. By prop. B.7 any null geodesic through p lying in Λ is (an extension of) a generator of $\tilde{\mathcal{N}}$ through p. Such a generator has a past endpoint on $int\tilde{S}_0 \subset int\Lambda$ and leaves $\tilde{\mathcal{N}}$ at the boundary of $\tilde{\mathcal{N}}$. Now recall that $\Lambda = \dot{I}^-[\tilde{\mathcal{N}}] \subset \overline{I^-[\tilde{\mathcal{N}}]}$. Lemma B.17 thus implies that the extension λ' of a generator as a null geodesic cannot remain in Λ outside $\tilde{\mathcal{N}}$. $\lambda' \cap \tilde{\mathcal{N}}$ thus has a future endpoint on the boundary of $\tilde{\mathcal{N}}$, which is contained in $int\Lambda$ since $\tilde{\mathcal{N}}$ is compact. By prop. B.10, and its time reverse, $I^+(p)$ and $I^-(p)$ intersect $D[\Lambda]$, so $p \in I^+(q) \cap I^-(r)$ with $q, r \in D[\Lambda]$. But it is easily shown that the whole open set

$I^+(q) \cap I^-(r)$ must be contained in $D[\Lambda]$, implying that $p \in intD[\Lambda]$. ∎

$\hat{\mathcal{V}} \equiv intD[\Lambda]$ is thus a globally hyperbolic boundaryless manifold which is a locally isometric covering of the original embedding of $\mathcal{N}$ in the arbitrary, smooth, Lorentzian, spacetime X. $\hat{\mathcal{V}}$ is sufficient spacetime to develop our whole theory in terms of the domain of dependence of $\mathcal{N}$. In particular we may define the domain of dependence of $\mathcal{N}$ in $\hat{\mathcal{V}}$, observables on this domain of dependence, and a Peierls bracket between these, which in turn induces our auxiliary pre-Poisson bracket on the initial data. Nevertheless $\hat{\mathcal{V}}$ does not in general contain the maximal Cauchy development of data given on $\mathcal{N}$. Even in a perfectly regular solution to Einstein's field equations a caustic may develop in the timelike geodesics normal to S_0 within the interior of the domain of dependence of $\mathcal{N}$. It is therefore interesting, though by no means necessary for the definition of the phase space or the Poisson structure on it, to show that a boundaryless manifold M extending $\hat{\mathcal{V}}$ can always be constructed that is globally hyperbolic and contains $\mathcal{N}$ and the interior of its maximal Cauchy development.

M is constructed by gluing two manifolds: Choose a Cauchy surface Σ_0 of $\hat{\mathcal{V}}$ lying to the future of $\mathcal{N}$.[79] The chronological past $I^-[\Sigma_0]$ of Σ_0 in $\hat{\mathcal{V}}$, denoted $\mathcal{A}$, is one of the components of M, which of course contains $\mathcal{N}$. The other component is obtained as follows. Choose a spacelike Cauchy surface Σ of the interior of the domain of dependence of $\mathcal{N}$ in $\mathcal{A}$, $\mathcal{D}_0 = intD[\mathcal{N}; \mathcal{A}]$. (Note that $\mathcal{D}_0 = intD[\mathcal{N}; \hat{\mathcal{V}}] \cap I^-[\Sigma_0; \hat{\mathcal{V}}]$.) If the metric on $\mathcal{D}_0$ satisfies the field equations then it induces admissible, spacelike, initial data on Σ, which in turn define a maximal Cauchy development $\mathcal{D}_m$. $\mathcal{D}_m$ is the other component of M.

$\mathcal{D}_0$ must be isometric to a subset of $\mathcal{D}_m$. Indeed

Lemma B.18 *There exists an isometry $\omega : \mathcal{D}_0 \cup \sigma_0 \to \mathcal{D}_m$ where $\sigma_0 = \Sigma_0 \cap intD[\mathcal{N}; \hat{\mathcal{V}}]$. Moreover, $\sigma_0' \equiv \omega[\sigma_0]$ is the border $\dot{\omega}[\mathcal{D}_0]$ in $\mathcal{D}_m$.*

Proof: The definition of the maximal Cauchy development implies that there exists an isometry $\omega : \mathcal{D}_0 \to \mathcal{D}_m$. This isometry extends to boundary points of $\mathcal{D}_0' \equiv \omega[\mathcal{D}_0]$ in $\mathcal{D}_m$, for all such boundary points are naturally images of points on the boundary of $\mathcal{D}_0$ in $\hat{\mathcal{V}}$: Suppose $p' \in \mathcal{D}_0'$, and γ' is a (future or past directed) timelike curve in $\mathcal{D}_0'$ which is inextendible in $\mathcal{D}_0'$ but has an endpoint in the direction of increasing curve parameter at p'. A timelike curve through $\mathcal{D}_0$ that is inextendible in $\hat{\mathcal{V}}$ must pass through the Cauchy surface $\mathcal{N}$ of $\mathcal{D}_0$ to the past and the Cauchy surface Σ_0, of $\hat{\mathcal{V}}$, to

[79] By [HE73] prop. 6.6.8. there exists a continuous "time" function t on $\hat{\mathcal{V}}$ which increases strictly to the future along any causal curve, and ranges from $-\infty$ to ∞. Since $\mathcal{N}$ is compact t has a finite maximum on $\mathcal{N}$. Any level set of t with t greater than this maximum will serve as the desired Cauchy surface.

the future, it cannot remain in $\mathcal{D}_0$. Thus $\gamma = \omega^{-1}[\gamma']$ must either have an endpoint in the sense of increasing parameter value inside $\mathcal{D}_0$ (but it cannot because γ' does not end inside $\mathcal{D}'_0$), or at a point p on the boundary of $\mathcal{D}_0$ in $\hat{\mathcal{V}}$.

Now choose a convex normal neighbourhood U_p of p in $\hat{\mathcal{V}}$ and a convex normal neighbourhood $U_{p'}$ of p' in $\mathcal{D}_m$. γ is contained U_p for sufficiently large curve parameter and $\gamma' = \omega[\gamma]$ is contained in $U_{p'}$ for sufficiently large parameter values. Thus $Y' = U_{p'} \cap \omega[U_p \cap \mathcal{D}_0]$ contains γ' beyond a minimum parameter value. Let $r' \in \gamma' \cap Y'$ and construct Riemann normal coordinates y' on $U_{p'}$ based at r'. Then define y to be the chart on U_p obtained by first pulling back y', restricted to a convex normal neighbourhood of r' contained in Y', to U_p via ω, and then extending the resulting Riemann normal coordinates about $r = \omega^{-1}(r')$ to all of U_p. This defines a diffeomorphism $\phi = y'^{-1} \circ y$ from part of U_p to part of $U_{p'}$.

The boundary of $\mathcal{D}_0$ in $\hat{\mathcal{V}}$ consists of the achronal hypersurface $\overline{\mathcal{D}_0} - I^-\mathcal{D}_0$ to the future and the achronal hypersurface $\overline{\mathcal{D}_0} - I^+\mathcal{D}_0 = \mathcal{N}$ to the past. Define I° to be $I^+(r; U_p)$ if p lies on the future boundary, and $I^-(r; U_p)$ if p lies on the past boundary. Since the geodesics from r to a point in $I^\circ \cap \mathcal{D}_0$ are entirely contained in $\mathcal{D}_0$ ϕ coincides with ω on $I^\circ \cap \mathcal{D}_0$. $y \circ \gamma$ and $y' \circ \gamma'$ thus define the same curve (for sufficiently large parameter value) in $\mathbb{R}^4$, and, since the limit points p and p' lie in the domains of y and y' respectively, $y(p) = y'(p')$. p therefore lies in the domain of ϕ and $\phi(p) = p'$. Indeed a whole neighbourhood W_p of p lies in the domain of ϕ, which is open. Since $p \in I^\circ$ this neighbourhood may be taken to lie inside I°. On W_p ϕ is then a smooth extension of ω. Moreover, since the metric is smooth in both of the charts y and y' it is an isometry on the closure of $\mathcal{D}_0$ in W_p.

Covering $\dot{\mathcal{D}}'_0$ with sets of the form $W_{p'} = \omega[W_p]$ a unique extension of ω^{-1} to $\dot{\mathcal{D}}'_0$ is obtained by patching together the maps $\phi^{-1} = y^{-1} \circ y'$. The extension is well defined and unique because any two diffeomorphisms extending ω^{-1} must agree on $\bar{\mathcal{D}}'_0$ in the overlap of their domains, since they agree on $\mathcal{D}'_0$ in the overlap of their domains. The extension is an isometry, and its inverse, which extends ω to part of $\dot{\mathcal{D}}_0$, will be called ω as well.

What part of $\dot{\mathcal{D}}_0$ lies in $\omega^{-1}[\dot{\mathcal{D}}'_0]$? A boundary point p' of $\mathcal{D}'_0$ in $\mathcal{D}_m$ that lies to the past of $\Sigma' = \omega[\Sigma]$ must be the image of a point $p \in \mathcal{N}$. (By prop. B.11.) Through p' there must therefore pass a null geodesic which is the isometric image of a portion of a generator through p. This null geodesic would be future inextendible but would not cross Σ', since the generator crosses $\bar{\Sigma}$ only at its future endpoint on $\partial\mathcal{N}$, which is not contained in $\Sigma \subset \mathcal{D}_0$, by prop. B.9. However Σ' is a Cauchy surface of $\mathcal{D}_m$. Thus there can be no boundary point to the past of Σ'.

A boundary point p' to the future of Σ' must be the image of a point p lying either on the future Cauchy horizon $H^+[\Sigma; \mathcal{A}]$ of Σ in $\mathcal{A}$, or on the future boundary, Σ_0, of $\mathcal{A}$ itself. If p lies on $H^+[\Sigma; \hat{\mathcal{V}}] \supset H^+[\Sigma; \mathcal{A}]$ there would be a past inextendible null

geodesic from p' which does not cross Σ', for through p there must exist, by theorem 8.3.5. of [Wald84], a null geodesic contained in $H^+[\Sigma;\hat{\mathcal{V}}] \subset J^+[\Sigma;\hat{\mathcal{V}}]$ which is past inextendible or has past endpoint on the causal edge of $\bar{\Sigma}$.[80] But the causal edge of $\bar{\Sigma}$ cannot be included in Σ since Σ', being a Cauchy surface contained in $\mathcal{D}_m$, has empty causal edge (by [Wald84], corollary to prop. 8.3.6.). p therefore does not lie in $H^+[\Sigma;\hat{\mathcal{V}}]$.

A future directed timelike curve from $\mathcal{D}_0$ cannot cross Σ_0 without crossing $H^+[\Sigma;\hat{\mathcal{V}}]$ - and thus leaving $intD[\mathcal{N};\hat{\mathcal{V}}]$ - first, except by passing through $\sigma_0 = \Sigma_0 \cap intD[\mathcal{N};\hat{\mathcal{V}}]$. $\sigma_0' = \omega[\sigma_0]$ thus contains the boundary of $\mathcal{D}_0'$ in $\mathcal{D}_m$. Moreover, all points of σ_0 are in fact mapped into $\mathcal{D}_m$: Consider using a different Cauchy surface, $\tilde{\Sigma}_0$, of $\hat{\mathcal{V}}$, lying to the future of Σ_0, in place of Σ_0 in our construction. The set $\tilde{\mathcal{D}}_0 = intD[\mathcal{N};\hat{\mathcal{V}}] \cap I^-[\tilde{\Sigma}_0;\hat{\mathcal{V}}]$, which contains $\mathcal{D}_0$ and in particular σ_0, would then be mapped by an isometry $\tilde{\omega}$ into $\mathcal{D}_m$. The $\tilde{\omega}$ may be chosen so that it agrees with ω on the overlap of their domains, including σ_0[81] ω thus maps all of σ_0 into $\mathcal{D}_m$. ∎

M is the union of $\mathcal{A}$ and $\mathcal{D}_m$ with points in $\mathcal{D}_0$ and $\mathcal{D}_m \cap I^-[\Sigma_0']$ identified according to the isometry ω. The open sets of M are those sets which have open intersections with $\mathcal{A}$ and $\mathcal{D}_m$ in the topologies of those manifolds. (This is the standard "gluing topology").

Proposition B.19 *M is Hausdorff*

Proof: Suppose M is not Hausdorff. Then there must exist points p and q in M such that all neighbourhoods of q intersect all neighbourhoods of p. If both p and q lie in $\mathcal{D}_m$, or both lie in $\mathcal{A}$ this cannot occur because $\mathcal{D}_m$ and $\mathcal{A}$ are Hausdorff. Suppose therefore that $q \in \mathcal{D}_m$ and $p \in \mathcal{A}$. $\mathcal{D}_m$ is thus a neighbourhood of q and $\mathcal{A}$ a neighbourhood of p, so in order that the pair violate the Hausdorff condition it is necessary that $q \in \dot{\mathcal{A}} = \dot{\mathcal{D}}_0' = \sigma_0'$ (by lemma B.18) in $\mathcal{D}_m$ and $p \in \dot{\mathcal{D}}_m = \dot{\mathcal{D}}_0$ in $\mathcal{A}$. To show that M is actually Hausdorff it is thus sufficient to find disjoint neighbourhoods of q and p in M for such p and q.

Let $q_0 = \omega^{-1}(q)$. By lemma B.18 $q_0 \in \sigma_0 \subset \dot{intD}[\mathcal{N};\hat{\mathcal{V}}]$ which is necessarily distinct from p lying in the disjoint set $\dot{\mathcal{D}}_0 \subset D[\mathcal{N};\hat{\mathcal{V}}]$. Since $\hat{\mathcal{V}}$ is Hausdorff there exist disjoint open subsets of $\hat{\mathcal{V}}$ $U_{q_0} \ni q_0$ and $U_p \ni p$. Indeed we can, and will, require that $U_p \subset \mathcal{A}$ and $U_{q_0} \subset intD[\mathcal{N};\hat{\mathcal{V}}] \cap I^-[\tilde{\Sigma}_0,\hat{\mathcal{V}}]$, where, as in the proof of lemma B.18, $\tilde{\Sigma}_0$ is a Cauchy surface of $\hat{\mathcal{V}}$ lying to the future of Σ_0.

[80] The causal edge is defined in [HE73] p.202. In $\hat{\mathcal{V}}$, which is globally hyperbolic, and thus strongly causal, $edge[\Sigma] = \partial\mathcal{N}$. See [HE73] p. 196-197 on Alexandrov topology.

[81] $\tilde{\omega} \circ \omega^{-1}$ defines an isometry of $\mathcal{D}_0'$ to another open subset of $\mathcal{D}_m$. Since $\mathcal{D}_0'$ contains Σ' the unicity of the maximal Cauchy development implies that this isometry extends to an isometry of $\mathcal{D}_m$ to $\mathcal{D}_m$. If this isometry is non-trivial one may simply compose its inverse with $\tilde{\omega}$ to obtain a new $\tilde{\omega}$, satisfying all requirements, which agrees with ω on $\mathcal{D}_0$.

The desired neighbourhoods of p and q in M are constructed from U_{q_0} and U_p. An open set in M is a pair of open sets, one in $\mathcal{A}$, one in $\mathcal{D}_m$, such that identified pairs of points are either both in the sets or both outside. Let $\tilde{\omega}$ be the isometry of lemma B.18 corresponding to the case in which Σ_0 is replaced by $\tilde{\Sigma}_0$, and recall from the proof of that lemma that $\tilde{\omega}$ may be chosen so that it agrees with ω on the intersection of their domains. With this choice of $\tilde{\omega}$ $\tilde{\omega}[U_{q_0}]$ is an open neighbourhood of q in $\mathcal{D}_m$, and $(U_{q_0} \cap \mathcal{D}_0, \tilde{\omega}[U_{q_0}])$ and $(U_p, \omega[U_p \cap \mathcal{D}_0])$ are disjoint open neighbourhoods of p and q are respectively. ∎

The paracompactness and time orientability of M follows from that of $\mathcal{A}$ and $\mathcal{D}_m$ and the fact that $\mathcal{D}_m \cap \mathcal{A}$ has only one connected component. (See [HE73] p. 14.)

Proposition B.20 *Λ (and thus $\mathcal{N}$) is achronal in M, and M is globally hyperbolic.*

Proof: Suppose $p \in \Lambda$ and γ is a future directed timelike curve from p. If γ remains in $\mathcal{A} \subset \hat{\mathcal{V}}$ it cannot cross Λ again because Λ is achronal in $\hat{\mathcal{V}}$. If γ leaves $\mathcal{A}$ without leaving M it must cross the boundary, Σ_0', of $\mathcal{A} \cap \mathcal{D}_m$ in $\mathcal{D}_m$. If γ is then to return to $\mathcal{A}$ it must again cross this same boundary, this time entering $\mathcal{A}$. But γ, which is future directed, cannot cross the boundary in both directions since Σ_0 is a level set of a time function which increases along any future directed causal curve. Thus γ cannot cross $\Lambda \subset \mathcal{A}$ a second time. This establishes the achronality of Λ in M.

To prove global hyperbolicity it is thus sufficient to show that all of M lies in the domain of dependence of Λ. Suppose γ is an inextendible causal curve which passes through $\mathcal{A}$. γ may be extended to an inextendible causal curve, γ', in $\hat{\mathcal{V}}$, and γ' must pass through Λ and through Σ_0. Since Σ_0 is achronal γ' cannot reenter $\mathcal{A}$ once it leaves, so $\gamma' \cap \mathcal{A} = \gamma$, proving that γ crosses Λ. If on the other hand γ is an inextendible causal curve passing through $\mathcal{D}_m$ then it must cross the Cauchy surface Σ of $\mathcal{D}_m$, which lies in $\mathcal{A}$, implying that γ also passes through $\mathcal{A}$ and thus through Λ. All inextendible causal curves in M cross Λ. ∎

The demonstration that only those points in $\mathcal{N}$ that lie on the same generator are causally related (prop. B.7) goes through in M precisely as in $\mathcal{V}$.

Since M (and $\hat{\mathcal{V}}$) are globally hyperbolic the transverse gauge linearized Einstein field equations (13) has unique advanced and retarded Green's functions $G^{\pm}(p, q)$ supported (as distributions) at points $q \in J^{\pm}(p)$. (see [CDD82] p. 523)

Using the global hyperbolicity of the ambient spacetime M or $\hat{\mathcal{V}}$ it may be shown that sources with compact support in the interior of $D[\mathcal{N}]$ do not perturb (to linear order) the metric in a spacetime neighbourhood of $\partial\mathcal{N}$:

Proposition B.21 *If s is a compact subset of the interior of the domain of dependence of $\mathcal{N}$ in M, then $J^{\pm}[s]$ is closed and disjoint from an open neighbourhood of $\partial\mathcal{N}$.*

Proof: The fact that $J^{\pm}[s]$ is closed follows from [HE73] prop. 6.6.1. To prove that $J^{\pm}[s]$ is disjoint from an open neighbourhood of $\partial\mathcal{N}$ it is therefore sufficient to show that it is disjoint from $\partial\mathcal{N}$ itself. Now by prop. B.15, prop. A.2, and lemma B.9 $I[\partial\mathcal{N}]$ is disjoint from $D[\mathcal{N}]$, and thus $\overline{I[\partial\mathcal{N}]} \supset J[\partial\mathcal{N}]$ is disjoint from $intD[\mathcal{N}]$. It follows at once that $J[s] \supset J^{\pm}[s]$ is disjoint from $\partial\mathcal{N}$. ∎

All Cauchy developments of $\mathcal{N}$ seem to be diffeomorphic to each other as spacetimes (though of course not necessarily isometric). In the following a slightly weaker claim, that they are diffeomorphic everywhere except possibly on their future Cauchy horizons (i.e. their future boundaries, see [HE73]), will be proved. This result makes possible the concrete representation we have used of the set of Cauchy developments as a space of solutions $\mathcal{S}$ to the field equations on a common, fixed manifold $\underline{\mathcal{D}}_0$ (The union of the interior of the hypersurface $\mathcal{N}_0 = \{t = |x|, |x| \leq 1, y^2 + z^2 \leq 1\}$ and the interior of its domain of dependence in $\mathbb{R}^4$ equipped with the Minkowski metric $ds^2 = -dt^2 + dx^2 + dy^2 + dz^2$ - see Fig. 2).

This representation makes the set of Cauchy developments easier to think about, but it is actually not necessary for our main results, which concern the Peierls bracket, the symplectic 2-form, and the auxiliary pre-Poisson bracket on the initial data. These objects are defined entirely in terms of first order perturbation theory about a given solution, and thus in the context of a single, spacetime manifold, fixed once this solution is chosen. The use of a fixed spacetime manifold in developing the main results of the present work is thus justified quite independently of the diffeomorphism between Cauchy developments.

Suppose $\mathcal{N}$ (defined as on p. 5) is smooth and achronal in a smooth, Lorentzian metric 4-manifold. Let us define $\underline{\mathcal{D}} = intD[\mathcal{N}] \cup int\mathcal{N}$. Then

Proposition B.22 *$\underline{\mathcal{D}}$ is the domain of dependence of $\mathcal{N}$ minus its future Cauchy horizon*

Proof: $D[\mathcal{N}] = D^+[\mathcal{N}]$ follows from prop. B.11, and prop. B.11 and prop. B.7 together imply that $int\mathcal{N} = I^-[D[\mathcal{N}]] \cap \mathcal{N}$. Thus the identities $intD[\mathcal{N}] = I^-[D[\mathcal{N}]] \cap I^+[D[\mathcal{N}]]$ and $D^+[\mathcal{N}] = D^+[\mathcal{N}] \cap I^+[\mathcal{N}] \cup \mathcal{N}$ imply $\underline{\mathcal{D}} = D[\mathcal{N}] \cap I^-[D[\mathcal{N}]]$, or equivalently $\underline{\mathcal{D}} = D[\mathcal{N}] - H^+[\mathcal{N}]$ where $H^+[\mathcal{N}] \equiv D[\mathcal{N}] - I^-[D[\mathcal{N}]]$ is the future Cauchy horizon. ∎

Proposition B.23 *For any two Cauchy developments, 1 and 2, of $\mathcal{N}$, $\underline{\mathcal{D}}_1$ and $\underline{\mathcal{D}}_2$ are diffeomorphic as manifolds (though not necessarily isometric).*

Proof: To prove diffeomorphism a smooth chart $\Phi : \underline{\mathcal{D}} \to \mathbb{R}^4$ is constructed for each Cauchy development, such that the range, $\Phi[\underline{\mathcal{D}}]$, of the coordinates on $\underline{\mathcal{D}}$ is the

same for all Cauchy developments. Then, if Φ_1 and Φ_2 are the charts for Cauchy developments 1 and 2 respectively, $\Phi_1^{-1} \circ \Phi_2$ provides the desired diffeomorphism.

The construction of the chart Φ proceeds in two steps. First the chart Φ is defined on a neighbourhood of S_0 and on $\mathcal{N}$ itself. Then this chart is extended to all of $\underline{\mathcal{D}}$. The exponential map f from the normal bundle O' over S' to to the ambient spacetime X is a smooth immersion except at degenerate points of df.

Since df is non-degenerate on $S' \supset S_0$, the generalized inverse function theorem ([AR67], p. 19) implies that f maps an open neighbourhood U of S' in O' diffeomorphically to a neighbourhood $\mathcal{U} = f[U]$ of S' in X. Moreover, $\mathcal{N} = f[N]$ where $N \subset O'$ is free of degenerate points of df. Since $\mathcal{N}$ is achronal f must be one to one on N and thus a diffeomorphism on this set as well.

Coordinates (x^0, x^1, x^2, x^3) are chosen on the normal bundle O' as follows: (x^2, x^3) coordinatize the base manifold S', and (x^0, x^1) the fibres, consisting of the normal vectors at each point of S'. (x^0, x^1) are linear, that is, they are the components of the normal vectors with respect to some basis defined at each point of S', and (x^0, x^1, x^2, x^3) are chosen so that $intN$ corresponds to the coordinate domain $\{(x^0, x^1, x^2, x^3) | |x^1| = x^0, |x^1| < 1, (x^2)^2 + (x^3)^2 < 1\}$.

Φ maps each point $p \in \mathcal{U} \cup \mathcal{N}$ to the coordinates (x^0, x^1, x^2, x^3) of its preimage $P = f|_U^{-1}(p)$ in $U \cup N$.

Note that the definition of the coordinates implies that the vector field ∂_0 on S_0 is timelike and future directed.

We turn now to the extension of Φ'. Since the continuous vector field ∂_0 is timelike and future directed on S_0 it is also so in an open neighbourhood $\mathcal{B}_0$ of S_0 in $\mathcal{U}$. Let $\mathcal{C}$ be a compact subset of $\mathcal{B}_0$ containing S_0 in its interior, then Φ will be set equal to Φ' on a compact subset $\mathcal{C}$ of $\mathcal{B}_0$ containing S_0 in its interior, and on $\mathcal{N}$ itself . To extend the chart beyond this set ∂_0 will first be extended to a smooth timelike vector field on all of $\underline{\mathcal{D}}$ by splicing it smoothly with a smooth, non-zero, future directed, future complete, timelike vector field on $\underline{\mathcal{D}}$. Here "future complete" means that the supremum of the curve parameter in $\underline{\mathcal{D}}$ is infinite on every integral curve of the vector field.

A field u satisfying these requirements can be found using a suitable Riemannian metric on $\underline{\mathcal{D}}$: Choose a partition of unity $\{f_n\}$ of $\underline{\mathcal{D}}$ subordinate to a locally finite atlas $\{\phi_n\}$ such that the domain of each chart ϕ_n has compact closure, and define the Riemannian metric $r = \sum_n f_n \phi_{*n} e$, the sum of the pullbacks via the various charts of the standard euclidean metric e on $\mathbb{R}^4$ weighted by the partition of unity. Let $\rho = \sum_n n f_n$. It is easy to show that the Riemannian metric $r' = r(||\nabla\rho||^2 + 1)$ is complete in the sense that any curve without endpoint in $\underline{\mathcal{D}}$ has infinite length, whereas a curve from a starting point to an end point, including starting and endpoints on $\mathcal{N}$, has

finite length.[82] u is taken at each point to be the future directed timelike vector of maximal proper time among the unit vectors of r'. The smoothness of r and the Lorentzian spacetime metric guarantee that this u is smooth.

The splicing is defined using a partition of unity φ_0, φ_1 subordinate to the cover $\mathcal{B}_0$, $\mathcal{B}_1 = \mathcal{U} - \mathcal{C}$. That is, φ_0 is a smooth function taking values between 0 and 1 such that $\varphi_0 = 1$ on $\mathcal{C}$ and 0 outside $\mathcal{B}_0$, and $\varphi_1 = 1 - \varphi_0$. $w = \varphi_0 \partial_0 + \varphi_1 u$ is the spliced field, defined on all of $\underline{\mathcal{D}}$ (for this it is sufficient that ∂_0 is defined on the support φ_0). Since both vector fields being added are timelike and future directed, so is their sum w.

Because w is timelike and non-zero on $\underline{\mathcal{D}}$ the integral curves of w are timelike and can have no endpoint in $int\underline{\mathcal{D}} = \underline{\mathcal{D}} - \mathcal{N}$. Every integral curve must therefore cross the Cauchy surface $\mathcal{N}$, precisely once. Indeed lemma B.9 prop. B.11 and lemma B.9 show that the set of points of $\mathcal{N}$ at which these integral curves cross is precisely $int\mathcal{N}$.

At a point $p \in \underline{\mathcal{D}}$ the coordinate x^0 of the extended chart Φ is the parameter of the integral curve of w through p, with zero set so that it agrees with the x^0 of the chart Φ on $\mathcal{N}$. The coordinates x^1, x^2, x^3 assigned to p by Φ are just the x^1, x^2, x^3 assigned by Φ' to the point at which the integral curve through p crosses $\mathcal{N}$. (That is, x^1, x^2, x^3 are held constant along the integral curves.)

The smoothness of w, of the submanifold $\mathcal{N} - S_0$ and of the chart Φ', on $\mathcal{U}$ and on $\mathcal{N} - S_0$, imply, via standard theorems on the solutions of ODEs, that Φ is a smooth chart of $\underline{\mathcal{D}}$.[83] By prop. B.11 $D[\mathcal{N}] = D^+[\mathcal{N}]$ so the value of x^0 on $\mathcal{N}$, equal to $|x^1|$ is the lower bound of the range of x^0 on a given integral curve, while the future completeness of u implies that the upper bound is ∞.

The range of Φ on $\underline{\mathcal{D}}$ is therefore

$$\Phi[\underline{\mathcal{D}}] = \{(x^0, x^1, x^2, x^3) | |x^1| \leq x^0 < \infty, |x^1| < 1, (x^2)^2 + (x^3)^2 < 1\}, \tag{350}$$

which is independent of the particular Cauchy development in question. ∎

[82] To show this note that the length of a curve exceeds the absolute value of the integral of $\nabla\rho$ along the curve. The claim then follows from the fact that ρ diverges along any curve without endpoint.

[83] The definition of w, and thus Φ extends to an open neighbourhood of $\underline{\mathcal{D}}$ in the ambient spacetime. The local existence and uniqueness theorem 21.1 of [AR67] implies that Φ is one to one. Theorem 21.2 (flow box theorem) of [AR67] shows that Φ is smooth and $d\Phi$ is invertible. Thus, by [CDD82] p. 93 theorem 1, Φ is a diffeomorphism of an open set containing $\underline{\mathcal{D}}$ into $\mathbb{R}^4$.

C Solutions to linearized gravity in terms of initial data and the relation between the variations of observables and the presymplectic 2-form

The key result of subsection 2.2.1, equation (33), can be proved in a less abstract manner, as a corollary to a Kirchhoff type formula for the solutions of the linearized Einstein equations in terms of initial data. This formula, demonstrated in the sequel, provides us with some analytic information about the dependence of the metric, and the observables, on initial data.

We begin by examining (33). As in subsection 2.2.1 we chose a spacetime region Q bounded by $\mathcal{N}$ and a Cauchy surface Σ_+ of the future domain of dependence of $\mathcal{N}$, so that the domain of sensitivity of A lies in the interior of Q. Then

$$\delta A = \int_Q \alpha^{\mu\nu} \delta g_{\mu\nu} \sqrt{-g} d^4x. \tag{351}$$

The perturbation $\Delta_A g$ of the metric induced by A is determined only modulo a diffeomorphism generator, but if we require it to obey the transverse gauge condition then, by (8) and (9), it may be written as

$$\Delta_A g_{\sigma\tau}(y) = -16\pi G \int_Q \alpha^{\mu\nu}(x) \Delta_{\mu\nu\,\sigma\tau}(x,y) \sqrt{-g} d^4x. \tag{352}$$

(33) thus holds for all observables of $\mathcal{D} = int\underline{\mathcal{D}}$ if, for all solutions to the linearized vacuum Einstein equations δg,

$$\delta g_{\mu\nu}(x) = -16\pi G \Omega_{\mathcal{N}}[\mathbf{\Delta}_{\mu\nu}(x), \delta] + 2\nabla_{(\mu}\xi_{\mu)} \tag{353}$$

at all points x of $\mathcal{D}$, for some vector field ξ. Here $\mathbf{\Delta}_{\mu\nu}(x)$ is the tensor field (depending on y) obtained from the two point tensor $\Delta_{\mu\nu\,\sigma\tau}(x,y)$ when x, μ, and ν are held fixed. The ξ term reflects the freedom to change δg by a linearized diffeomorphism. When both sides of (353) are integrated against α to recover (33) it disappears because α is divergenceless and vanishes at the boundary of integration. (Note that (353) implies that (33) holds even when Δ_A is not in transverse gauge, because, as (81) will show, when δ is a solution to the linearized field equations that vanishes near $\partial\mathcal{N}$ $\bar{\Omega}[\pounds_\xi, \delta] = 0$ for any diffeomorphism generator $\pounds_\xi$.)

Equation (353) is in fact valid: Suppose $\gamma_1 \equiv \delta_1 g$ is a solution to the linearized field equations that satisfies the transverse gauge condition, $\chi_\nu \equiv \nabla^\mu \bar{\gamma}_{\mu\nu} = 0$ with $\bar{\gamma}_{\mu\nu} = \gamma_{\mu\nu} - \frac{1}{2} g_{\mu\nu} g^{\sigma\rho} \gamma_{\sigma\rho}$, and let $\gamma_2 \equiv \delta_2 g$ be the (unique) advanced solution to the linear, diagonal, second order hyperbolic system

$$\nabla^\sigma \nabla_\sigma \bar{\gamma}_{\mu\nu} - 2R^\sigma{}_{\mu\nu}{}^\rho \bar{\gamma}_{\sigma\rho} = \theta_{\mu\nu}, \tag{354}$$

with θ a smooth, symmetric tensor field of compact support contained in $\mathcal{D}$. (This equation is just (13) with the source $32\pi G\alpha$ replaced by θ.) γ_2 may be expressed in terms of the advanced Green's function as

$$\gamma_{2\,\sigma\tau}(y) = -\frac{1}{2}\int_Q \theta^{\mu\nu}(x) G^-_{\mu\nu\,\sigma\tau}(x,y)\sqrt{-g}d^4x. \tag{355}$$

Here Q is defined as earlier, but with future boundary chosen so that Q contains the support of θ. Note that G^- is *regular* in the sense that when it is integrated against a smooth source θ the result is a smooth solution [CDD82].

Now, for any variation δ the variation of the Einstein tensor is

$$\delta G_{\mu\nu} = \nabla_{(\mu}\chi_{\nu)} - 1/2 g_{\mu\nu}\nabla_\sigma\chi^\sigma - 1/2(\nabla^\sigma\nabla_\sigma\bar{\gamma}_{\mu\nu} - 2R^\sigma{}_{\mu\nu}{}^\rho\bar{\gamma}_{\sigma\rho}), \tag{356}$$

so γ_2 would be a solution to the linearized Einstein equations, with source $-\frac{1}{2}\theta$, if $\chi_{2\,\nu}$ were zero.

However, (354) and the Bianchi identity imply that

$$\nabla^\mu\nabla_\mu\chi_{2\,\nu} = \nabla^\mu\theta_{\mu\nu}, \tag{357}$$

implying that χ_2 does not vanish unless θ is divergenceless - which is not assumed here. (357) also has unique, regular retarded and advanced Green's functions $H^\pm$. Hence

$$\chi_{2\,\tau}(y) = \int_Q \nabla_\mu\theta^{\mu\nu}(x)H^-_{\nu\,\tau}(x,y)\sqrt{-g}d^4x \tag{358}$$

$$= -\int_Q \theta^{\mu\nu}(x)\nabla_\mu H^-_{\nu\,\tau}(x,y)\sqrt{-g}d^4x \tag{359}$$

Now consider the identity used in (37) to prove the hypersurface independence of $\bar{\Omega}$:

$$0 = \delta_1\delta_2 I - \delta_2\delta_1 I - [\delta_1,\delta_2]I \tag{360}$$

$$= \delta_1\phi[\delta_2] - \delta_2\phi[\delta_1] - \phi[[\delta_1,\delta_2]] \tag{361}$$

$$+\frac{1}{16\pi G}\int_Q [\delta_2 g_{\mu\nu}\delta_1 G^{\mu\nu} - \delta_1 g_{\mu\nu}\delta_2 G^{\mu\nu}]\sqrt{-g}\,d^4x \tag{362}$$

$$= -\bar{\Omega}_{\mathcal{N}}[\delta_1,\delta_2] - \frac{1}{16\pi G}\int_Q \delta_1 g_{\mu\nu}[\nabla^\mu\chi_2^\nu - \frac{1}{2}g^{\mu\nu}\nabla_\sigma\chi_2^\sigma - \frac{1}{2}\theta^{\mu\nu}]\sqrt{-g}\,d^4x. \tag{363}$$

In (363) the facts that $\delta_1 G^{\mu\nu} = 0$, that $\delta_2 g$ vanishes in a neighbourhood of the future boundary of Q, and that the orientation of $\mathcal{N}$ is opposite that of ∂Q have been taken into account. It is easy to obtain (33) directly from this last expression, by setting $\theta = 32\pi G\alpha$, but it is illuminating to press on to obtain an expression for $\delta_1 g$ in terms of data on $\mathcal{N}$.

The last integral of (363) can be written as

$$\int_Q \bar{\gamma}_{1\,\mu\nu} \nabla^\mu \chi^\nu \sqrt{-g}\, d^4x - \frac{1}{2} \int_Q \theta^{\mu\nu} \delta g_{\mu\nu} \sqrt{-g}\, d^4x. \tag{364}$$

Since γ_1 satisfies the transverse gauge condition, integrating the first term by parts reduces it to a boundary integral, in fact an integral over $\mathcal{N}$ only:

$$-\int_{\mathcal{N}} \bar{\gamma}_1^{\sigma\tau} \chi_{2\,\tau} \sqrt{-g}\, d\Sigma_\sigma = \int_Q \theta^{\mu\nu}(x) \nabla_\mu \xi_\nu \sqrt{-g}\, d^4x, \tag{365}$$

where

$$\xi_\nu(x) = \int_{\mathcal{N}} \bar{\gamma}_1^{\sigma\tau} H^-_{\nu\,\tau}(x,y) \sqrt{-g}\, d\Sigma_\sigma. \tag{366}$$

Now θ is an arbitrary smooth symmetric tensor field with support contained in $\mathcal{D}$ so (363), (364), and (366) imply that at any point p of $\mathcal{D}$

$$\delta_1 g_{\mu\nu}(p) = 16\pi G\, \Omega_{\mathcal{N}}[\mathbf{G}^-_{\mu\nu}(p), \delta_1] + 2\nabla_{(\mu}\xi_{\nu)}, \tag{367}$$

where $\mathbf{G}^-_{\mu\nu}(p)$ is the tensor field obtained by fixing the first argument point in the advanced Green's function to be p (and the pair of indices associated with the first point to be μ and ν). (353) follows immediately if one notes that the retarded Green's function $G^+(p,q)$ vanishes for $q \in \mathcal{N}$ since $\mathcal{N}$ lies outside $J^+(p)$.

Solutions to the linearized field equations that are *not* in transverse gauge only differ from transverse gauge solutions by a linearized diffeomorphism. Such solutions can thus also be expressed in terms of initial data via (367) or (353), by using ξ other than that defined by (366).

D $G_{rr} = 0$

In this appendix it is shown that on $\mathcal{N}_R$ the Einstein field equation $G_{rr} = 0$, in the adapted coordinates $a^\alpha = (u, r, y^1, y^2)$, is equivalent to

$$\Gamma^r_{rr} = -\frac{r}{8}\, \partial_r e_{ij}\, \partial_r e^{ij}. \tag{368}$$

We proceed by direct calculation of G_{rr}. The form (103) that the metric takes in the adapted coordinates implies that in these coordinates the Christoffel symbols,

$$\Gamma^\alpha_{\beta\gamma} = \frac{1}{2} g^{\alpha\epsilon} \{\partial_\gamma g_{\epsilon\beta} + \partial_\beta g_{\epsilon\gamma} - \partial_\epsilon g_{\beta\gamma}\}, \tag{369}$$

on $\mathcal{N}_R$ satisfy

$$\Gamma_{\alpha rr} = \delta^u_\alpha \Gamma_{urr}, \quad \Gamma^\alpha_{rr} = \delta^\alpha_r \Gamma^r_{rr} \tag{370}$$

$$\Gamma^r_{rr} = g^{ur}\Gamma_{urr} = \frac{1}{2}\partial_u g_{rr} \tag{371}$$

$$\Gamma_{r\beta r} = \delta^u_\beta \Gamma_{rur}, \quad \Gamma^u_{\beta r} = \delta^u_\beta \Gamma^u_{ur} \tag{372}$$

$$\Gamma^u_{ur} = g^{ur}\Gamma_{rur} = -\frac{1}{2}\partial_u g_{rr} = -\Gamma^r_{rr} \tag{373}$$

$$\Gamma^i_{jr} = \frac{1}{2}g^{ik}\partial_r g_{jk} = \delta^i_j \frac{1}{r} + \frac{1}{2}e^{ik}\partial_r e_{jk}, \quad \Gamma^i_{ir} = \frac{2}{r} \tag{374}$$

$$\partial_u \Gamma_{rrr} - \partial_r \Gamma_{rur} = \frac{1}{2}\{\partial_u\partial_r g_{rr} - \partial_r\partial_u g_{rr}\} = 0. \tag{375}$$

Using these facts, and the adapted coordinate form (103) of the metric, G_{rr} can be simplified as follows:

$$\begin{aligned}
G_{rr} = R_{rr} &\equiv \partial_\alpha \Gamma^\alpha_{rr} - \partial_r \Gamma^\alpha_{\alpha r} + \Gamma^\beta_{rr}\Gamma^\alpha_{\alpha\beta} - \Gamma^\beta_{\alpha r}\Gamma^\alpha_{\beta r} && (376)\\
&= \partial_u \Gamma^u_{rr} - \partial_r \Gamma^u_{ur} - \partial_r \Gamma^i_{ir} + \Gamma^r_{rr}\Gamma^\alpha_{\alpha r} - \Gamma^u_{ur}\Gamma^u_{ur} - \Gamma^r_{rr}\Gamma^r_{rr} && (377)\\
&\quad -\Gamma^i_{jr}\Gamma^j_{ir} && (378)\\
&= [\partial_u g^{uu}]\Gamma_{urr} + g^{ur}\partial_u\Gamma_{rrr} - [\partial_r g^{ur}]\Gamma_{rur} - g^{ur}\partial_r\Gamma_{rur} + \frac{2}{r^2} && (379)\\
&\quad +\Gamma^r_{rr}\Gamma^u_{ur} + \frac{2}{r}\Gamma^r_{rr} - \Gamma^u_{ur}\Gamma^u_{ur} - \frac{2}{r^2} - \frac{1}{4}e^{ik}e^{jl}\partial_r e_{jk}\partial_r e_{il} && (380)\\
&= -g^{ur}[\partial_u g_{rr}]\Gamma^r_{rr} + g^{ur}[\partial_r g_{ru}]\Gamma^u_{ur} + \Gamma^r_{rr}\Gamma^u_{ur} - \Gamma^u_{ur}\Gamma^u_{ur} && (381)\\
&\quad +\frac{2}{r}\Gamma^r_{rr} + \frac{1}{4}\partial_r e_{ij}\partial_r e^{ij} && (382)\\
&= \frac{2}{r}\Gamma^r_{rr} + \frac{1}{4}\partial_r e_{ij}\partial_r e^{ij}, && (383)
\end{aligned}$$

which implies the result.
